Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on their own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Editors assume any liability for any injury and/or damage to persons or property arising out or related to any use of the material contained in this book.

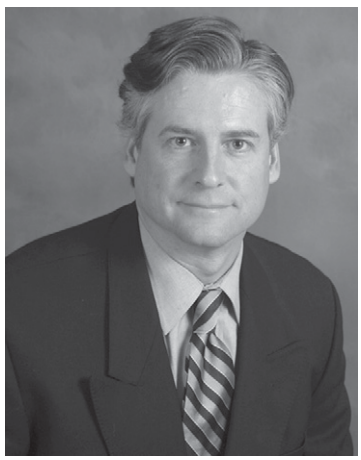
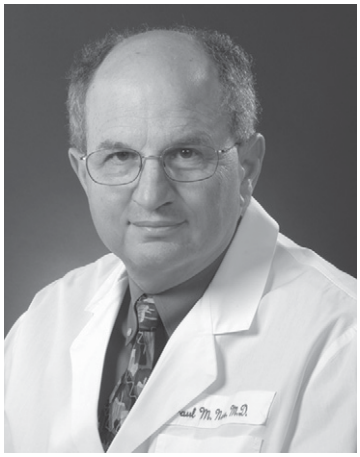
About the Editors



Dr. Hillyer is a tenured professor in the Departments of Pathology and Pediatrics, as well as the Division of Hematology/Oncology, Winship Cancer Institute, Emory University School of Medicine. He serves as director of the Transfusion Medicine Program at Emory and oversees the Emory University Hospital Blood Bank, the blood and tissue banks of Children's Healthcare of Atlanta, and the Emory Center for the Advancement of International Transfusion Safety. He is an editor of three textbooks on transfusion medicine and an author of more than 120 articles and chapters pertaining to transfusion, HIV, cytokines, and herpesviruses (most notably CMV). Nationally recognized as an expert in hematology and blood transfusion, Dr. Hillyer is President of AABB (2006–2007) and is a Trustee of the National Blood Foundation (NBF). He has been awarded research funding from the NIH, CDC, NBF, and other agencies. He currently serves as principal investigator of a program project grant, several R-series awards, the Emory site of the NHLBI's Transfusion Medicine/Hemostasis Clinical Trial Network, and REDS-II. He also is a co-principal investigator of AABB's contract with HHS to provide technical assistance to six developing nations under the President's Emergency Plan for AIDS Relief (PEPFAR). Dr. Hillyer is an associate editor of *Transfusion* and part-time medical director of the American Red Cross Southern Region. Dr. Hillyer is board certified in Transfusion Medicine, Hematology, Medical Oncology, and Internal Medicine. He received his BS from Trinity College and his MD from the University of Rochester School of Medicine, with postgraduate training and fellowships in hematology-oncology, transfusion medicine, and bone marrow transplantation at Tufts–New England Medical Center in Boston.

Dr. Silberstein is a tenured professor in the Department of Pathology, Harvard Medical School, and a Senior Investigator at the CBR Institute for Blood Research. He serves as director of the Joint Program in Transfusion Medicine, with responsibility for the blood and tissue programs at Boston Children's Hospital, the Brigham and Women's Hospitals, and the Dana-Farber Cancer Institute. Dr. Silberstein has recently created the Center for Human Cell Therapy at Harvard Medical School. The goal of this innovative center related to transfusion medicine is to facilitate the translation of proof-of-principle discoveries to clinical applications. Dr. Silberstein is editor of several texts, including *Hematology* and the *Handbook of Transfusion Medicine.* He is a member of the editorial boards of *Blood* and *Transfusion.* Dr. Silberstein is a highly respected physician-scientist well known for his mentorship; he has trained more than 45 fellows with PhD and MD backgrounds in transfusion medicine-related research. A leader and expert in transfusion medicine and hematology, Dr. Silberstein's research has focused on the immunology of B-cells and hematopoiesis, leading to the publication of more than 75 papers and numerous book chapters and reviews. Dr. Silberstein is board certified in Transfusion Medicine, Hematology, and Internal Medicine. He received his Baccalaureate and MD degrees from the University of Leiden, the Netherlands, and accomplished postgraduate training in Hematology/Oncology and Transfusion Medicine at Tufts–New England Medical Center in Boston.



Dr. Ness is director of the Transfusion Medicine Division at The Johns Hopkins Hospital and professor of Pathology, Medicine, and Oncology at The Johns Hopkins University School of Medicine. For many years he also acted as CEO and medical director of the Greater Chesapeake and Potomac Region of the American Red Cross Blood Services. Dr. Ness has served the AABB for a number of years and was President in 1999. He served on the editorial board of *Transfusion* until named Editor in 2003. Dr. Ness has been a member of the American Society of Clinical Pathologists Board of Registry Blood Bank examination committee, and the FDA Blood Products Advisory Committee, and he consults for many commercial and nonprofit organizations. He is the editor of several textbooks on transfusion medicine and has published more than 150 articles. Dr. Ness' research focuses on transfusion-related complications and has been funded by the NIH and CDC. He was involved in the initial REDS program and now acts as consultant to REDS-II. He serves as principal investigator for the Johns Hopkins site of the Transfusion Medicine/Hemostasis Clinical Trial Network, funded by NHLBI. Dr. Ness is co-principal investigator of a project funded by the REDS-II program to study donor virus epidemiology issues in China. He has worked extensively in international blood safety initiatives in China, Thailand, Vietnam, Botswana, and Nigeria. Dr. Ness received his undergraduate education at the Massachusetts Institute of Technology and his MD degree from the State University of New York at Buffalo. His postgraduate work includes residency in internal medicine at Johns Hopkins, fellowship training in hematology-oncology at the University of California, San Francisco, and a transfusion medicine fellowship at Irwin Memorial Blood Bank in San Francisco.

Dr. Anderson is the Kraft Family Professor of Medicine at Harvard Medical School and serves as chief of the Division of Hematologic Neoplasia, director of the Jerome Lipper Multiple Myeloma Center, and vice chair of the Joint Program in Transfusion Medicine at Dana-Farber Cancer Institute. Currently, Dr. Anderson is chair of the NCCN Multiple Myeloma Clinical Practice Guidelines Committee, is a Cancer and Leukemia Group B Principal Investigator, and is on the Board of Scientific Advisors of the International Myeloma Foundation. He has published more than 300 original articles and 200 book chapters, and has edited multiple textbooks on multiple myeloma and transfusion medicine. He is a Doris Duke Distinguished Clinical Research Scientist and has had long-term RO1, PO1, and SPORE funding from the NIH and other agencies. Dr. Anderson has received numerous awards, including the 2001 Charles C. Lund Award of the American Red Cross Blood Services, the 2003 Waldenstrom's award for research in plasma cell dyscrasias, the 2004 Johnson & Johnson Focused Giving Award for Setting New Directions in Science and Technology, and the 2005 Robert A. Kyle Lifetime Achievement Award. Dr. Anderson graduated from Johns Hopkins Medical School, trained in internal medicine at Johns Hopkins Hospital, and completed hematology, medical oncology, and tumor immunology fellowships at the Dana-Farber Cancer Institute.

Dr. Roback is a tenured associate professor in the Department of Pathology and Laboratory Medicine at Emory University, associate director of the Emory Transfusion Medicine Program, and co-director of the Emory University Hospital Blood Bank and Stem Cell Processing Laboratory. Dr. Roback's research focuses on human and animal models of CMV infection, emphasizing approaches to accelerate and improve the antiviral immune response following hematopoietic stem cell transplantation. He also is inventor or co-inventor of a number of novel devices and methodologies for rapid pretransfusion blood testing. Dr. Roback's investigations have been funded by the NIH, CDC, NBF, and DOD. He is a co-principal investigator of the Emory site for REDS-II. Dr. Roback has authored 40 peer-reviewed publications and invited reviews, as well as 16 book chapters. He teaches medical, residency, and graduate school courses and was recognized for excellent clinical pathology teaching with the Golden Apple Award. An active member of a number of AABB committees, Dr. Roback is editor-in-chief of the 16th edition of the AABB's Technical Manual, member of the editorial board for the journal *Transfusion*, and co-chair of the NHLBI's Global Blood Safety and Availability task force on future transfusion medicine research initiatives. He is a Diplomate of the American Board of Pathology in Clinical Pathology and Blood Banking and Transfusion Medicine. Dr. Roback received his Baccalaureate degree from Johns Hopkins University and was awarded a PhD in experimental pathology and an MD from the University of Chicago. He completed a postdoctoral research fellowship and anatomic pathology residency training at Albert Einstein College of Medicine and subsequently completed clinical pathology and transfusion medicine training at Emory University.

Preface to the Second Edition

The editors are pleased to introduce the Second Edition of *Blood Banking and Transfusion Medicine*. Substantial modifications and additions have been made to the text, reflecting advancements in a number of areas, including cellular therapy, component preparation, infectious disease testing, and the underlying biology of transfusion therapy. In addition, we have continued to integrate elements of Anderson and Ness's excellent textbook *The Scientific Basis of Transfusion Medicine*, which can be noted by the reader as a number of new chapters entitled "Principles of …." We are grateful for the many suggestions offered by readers of the First Edition that led to additional improvements in the text. We have made a concerted effort to ensure that each chapter includes the most up-to-date scientific underpinnings of transfusion biology as well as detailed information that can be applied to clinical transfusion practice. It is our goal that this textbook remain the definitive source of blood banking and transfusion medicine biology, technology, and practice for physicians, technologists, nurses, and administrative personnel, and we sincerely welcome readers' observations, criticisms, and suggestions so that we can continue to work to improve this book. Finally, we thank you for your support of this text, the field of transfusion medicine, and the patients we serve.

C. D. Hillyer

L. E. Silberstein

P. M. Ness

K. C. Anderson

J. D. Roback

Acknowledgments

We, the editors, would like to acknowledge the outstanding technical and professional support of Sue Rollins and the expertise, guidance, and friendship of Dolores Meloni. We would also like to thank our friends and families for their unconditional love and support, without which this edition could not have come to fruition. We thank especially Krista, Whitney, Peter, Margot, Jackson, and James Hillyer; the family and friends of Les Silberstein; Barbara, Jennie, Steven, and Molly Ness; Cynthia, Emily, David, and Peter Anderson; and Linda, Evan, and Ethan Roback. Finally, we would like to acknowledge and thank the many mentors, physicians, and patients who have served as inspiration, colleagues, and friends.

Chapter 1

A Brief History of Blood Transfusion

Kim A. Janatpour • Paul V. Holland

EARLY HISTORY

Since the beginning of human history, blood has been recognized as a vital force, the essence of life. Prehistoric man created cave drawings showing individuals bleeding from traumatic wounds. In the Bible, Leviticus states "the life of the flesh is in the blood." The Chinese Huang Di Nei Ching (770–221 BC) held that blood contained the soul. Blood played a central theme in ancient rituals. Egyptians and Romans took blood baths for physical and spiritual restoration,[1] and Romans even drank the blood of fallen gladiators in the belief that the blood could transmit the gladiator's vitality. Precolumbian North American Indians bled the body "of its greatest power" as self-punishment. In the Middle Ages, the drinking of blood was advocated as a tonic for rejuvenation and for the treatment of various diseases.[2] Pope Innocent VIII drank the blood from three young boys in 1492. Unfortunately, the boys and the Pope died.[2] The idea that infusion of blood could be beneficial did not emerge until the 17th century.

From the time of Hippocrates (c. 450 BC), disease was believed to be caused by an imbalance of the four humours—blood, phlegm, yellow bile, and black bile. Of these, blood was the most important (Galen [130–201 AD] really advanced the humoural theory). The most popular treatment for most ailments, even as late as the 18th century, was blood letting (Fig. 1–1). Without the correct understanding of blood circulation, intravenous blood infusion could not even be imagined. This changed in 1628 with William Harvey's description of the circulatory system. Harvey's identification of separate yet connected arterial and venous systems in his *De Motu Cordis* paved the way for an entirely new arena of blood investigation.[3]

In 1656, Christopher Wren used a quill with an attached bladder to demonstrate that the intravenous injection of substances into animals had systemic effects.[1,2] In 1666, Richard Lower successfully transfused blood from one dog to another, which led Samuel Pepys to speculate on the potential benefits of human transfusion, stating that "bad blood" might be mended by "borrowing" blood "from a better body."[3]

THE FIRST ANIMAL-TO-HUMAN TRANSFUSIONS

The first published animal-to-human transfusion was performed June 15, 1667, by Jean Baptiste Denis, a physician to Louis XIV, on a 16-year-old boy who had been "tormented with a contumacious and violent fever." The boy had been treated with multiple bleeds, following which "his wit seemed wholly sunk, his memory perfectly soft, and his body so heavy and drowsie that he was not fit for any thing." Denis attributed these symptoms to the bloodletting he had received. As treatment, Denis exchanged 3 ounces of the boy's blood for 9 ounces of lamb's blood. Denis chose animal blood because he believed it purer than that of humans due to man's "debauchery and irregularities in eating and drinking" and reasoned that if man could use animal milk as nutrient, animal blood would be safe. Following the infusion of lamb's blood, the patient complained about "a great heat along his arm," but otherwise suffered no ill effects. Denis subsequently performed such transfusions on three more patients, the last of which resulted in the first malpractice suit for blood transfusion.[4] Antoine Mauroy was a 34-year-old madman who was brought to Denis after he was found wandering the streets of Paris in the winter of 1667. Mauroy had suffered for years from severe "phrensies," during which he would beat his wife, strip off his clothes, and run through the streets, setting house fires. At this time, blood was believed to affect one's temperament and character; therefore, it was reasoned that blood transfusion could be used to treat mental ailments. Denis's patron, Monsieur de Montmort, proposed transfusing Mauroy to allay the "heat of his blood."[5] Denis transfused Mauroy with calf's blood, hoping that the calf's docile nature would be imparted to Mauroy. Although the patient complained of heat moving up his arm, he tolerated the transfusion well. A few days later, a second, larger transfusion was performed. This time, however, the patient complained "of great pains in his kidneys, and that he was not well in his stomack, that he was ready to [choak] unless they gave him his liberty."[6] The transfusion was quickly discontinued, after which the patient vomited and passed urine "black as soot." Miraculously, the patient not only survived this hemolytic transfusion reaction, but also appeared to be cured, showing "a surprising calmness, and a great presence of mind … and a general lassitude in all his limbs." In fact, upon seeing his wife a few days later, Mauroy greeted her tenderly, relating "with great presence of mind all that had befallen him." Denis was astonished—the man who "used to do nothing but swear and beat his wife" had dramatically, almost magically, been cured.[7]

Also, later in 1667, Richard Lower successfully transfused a Cambridge University student described as "cracked a little in the head" with sheep's blood.[3,4] A bitter debate followed between Denis and Lower as to who could claim to have discovered blood transfusion.[4]

Although a select group of scientists was excited about the concept of transfusion, others were adamantly opposed to the practice. Denis, in particular, suffered harsh criticism from his peers. With this intense debate and criticism as the backdrop, Mauroy suffered a relapse; his wife begged Denis to transfuse her husband again. Denis found the patient to be very ill, so was hesitant to perform the transfusion, but reluctantly agreed. Before the transfusion began, however, Mauroy died and his widow refused to allow Denis to examine the body. The widow had been offered money from Denis's rivals to charge him with murder; she offered to drop the matter if Denis would agree to support her financially. Denis refused, and the case went to court. Denis was exonerated when it was discovered that Mauroy had been poisoned with arsenic by his wife. Nonetheless, although Denis was acquitted of malpractice, the general opposition to transfusion ultimately led the French and English courts, and much of the rest of Europe, to ban all human transfusions.[1,4,5,7,8]

FIRST HUMAN-TO-HUMAN TRANSFUSION

After being banned for more than 150 years, the use of blood transfusion was revived during the late 18th century. A footnote in an American journal indicates that the first human-to-human transfusion had been performed by Philip Syng Physick, the "Father of American Surgery," in 1795, although this has never been confirmed.[5,9] In 1816, John Henry Leacock, a Barbados physician, presented his dissertation "On the Transfusion of Blood in Extreme Cases of Haemorrhage." Leacock subsequently performed and published a set of animal experiments that proved that the donor and recipient must be of the same species.[10]

Although Leacock apparently went no further with the experiments, his work inspired James Blundell, an obstetrician and physiologist at Guy's Hospital in London, to carry out additional investigations. At the time, obstetricians could only stand by and watch helplessly as patients exsanguinated postpartum. Blundell was convinced that blood transfusion

could save patients' lives. His extensive experimentation confirmed Leacock's findings that blood could be used to treat hemorrhagic shock, but only blood from the same species could be used. Recognizing the potentially serious risks of transfusion, Blundell began attempting human-to-human transfusion in cases that were otherwise hopeless. Over a decade, he performed 10 such transfusions, all without success. However, in August 1825, Blundell successfully transfused a woman dying from postpartum hemorrhage with blood from her husband. Other successes followed, including three cases of postpartum hemorrhage, and a young boy who was hypovolemic following amputation of his leg.[11] Subsequently, other reports of transfusion followed from Europe and then the United States, where it was reported that transfusion was used by the Union Army during the American Civil War.[5,9]

Significant progress in understanding the basis for the incompatibility between species was made by Emil Ponfick and Leonard Landois in the late 1800s.[8] The first revelation came from Ponfick, who observed red cell lysis in the blood of a woman who died after receiving a transfusion of sheep blood. From animal experiments, Ponfick found that incompatible transfusions were associated with hemorrhage and "congestion" of the kidneys, lungs, and liver. He also recognized that the red urine that transfused animals excreted was caused by hemoglobinuria, not hematuria. Landois's observation that human red cells would lyse when mixed in vitro with the sera of other animals set the stage for the study of the immunologic basis of blood incompatibility.[8]

DISCOVERY OF ABO BLOOD GROUPS

Before 1901, the prevailing belief was that all human blood was the same. However, this changed in 1901 with Karl Landsteiner's landmark discovery of ABO blood groups.[12] Landsteiner, an Austrian immunologist, noticed that human blood mixed in test tubes with other specimens of human blood sometimes resulted in agglutination. By incubating red cells from some individuals with serum from others, he identified agglutination patterns, leading to the initial identification of three blood groups, A, B, and C (C was later renamed O).[3,13] In 1902, Alfred Decastello and Adriano Sturli, two of Landsteiner's former students, found the fourth blood group, AB.[3] Landsteiner also contributed to forensic science by developing a method for blood typing of dried blood specimens.[14]

Interestingly, the importance of the blood groups was not immediately recognized; blood group typing did not become part of routine practice for several years. Richard Weil, a pathologist at the German Hospital in New York, was the first to perform ABO typing and began compatibility testing in 1907; he was also the first to suggest inheritance of ABO types.[5] Also in 1907 and 1910, respectively, Jan Jansky of Czechoslovakia and Moss of the United States independently identified four human blood groups.[3] However, the Roman numeral systems that Jansky and Moss each used for designating the four blood groups were completely reversed. Tremendous confusion ensued with the three different nomenclatures. Finally, in 1927, the American Association of Immunologists adopted a new classification scheme proposed by Landsteiner, the current ABO terminology.[3]

The discovery of blood groups led Ludvig Hektoen of Chicago to advocate selecting donors by blood group and crossmatching.[8] In 1913, Reuben Ottenberg conclusively demonstrated the importance of compatibility testing in his report of 128 cases of transfusion.[15] However, even as recently as 1937, some suggested that crossmatching was unnecessary if the selection of donors was restricted to individuals of the same blood group.[5]

The inheritance pattern of blood groups was finally proved by Felix Bernstein in 1924.[3] Sadly, differences in race distribution of blood groups were manipulated and misused in Germany during World War I (WWI) and World War II (WWII), during which time blood group B was deemed a marker for Slavic or Jewish race, and blood group A was considered associated with intelligence and industry. In the 1950s in Louisiana, it was a misdemeanor for a physician to give blood from a black donor to a white person without consent. In the United States, segregation of blood by race existed until the 1960s.[3]

DISCOVERY OF RH BLOOD GROUPS

Although a major discovery in transfusion medicine, ABO blood group typing was not sufficient to prevent many fatal hemolytic transfusion reactions. In 1939 Philip Levine published a case report of post-transfusion hemolysis in a blood group O patient who received blood from her blood group O husband. Levine found that incubation of the patient's serum with her husband's red cells resulted in agglutination. Additionally, the woman's serum was found to agglutinate 80 of 104 other samples of ABO-compatible blood. The name of the offending antibody came from parallel experiments conducted by Landsteiner and Alex Wiener in which antibodies produced by immunization of rabbits and guinea pigs with blood from rhesus monkeys caused red cell agglutination of 85% of humans tested. Those individuals whose red cells were agglutinated by these antibodies were classified as rhesus (Rh) positive.[3] Levine was able to show that Rh antibodies were the main cause of serious hemolytic disease of the newborn (erythroblastosis fetalis).[16] Later, it was appreciated that the Rh system is composed of numerous alleles. The current system of nomenclature—c, C, d, D, e, E—was proposed in 1944 by Cambridge geneticist Sir Ronald Fisher. Subsequent development of Rh immune globulin (RhIG) for prevention of hemolytic disease of the newborn was a major advance. The use of the antiglobulin test, first described by Carlo Moreschi in 1908 and rediscovered in 1945 by Robin Coombs, Rob Race, and Arthur Mourant, allowed the identification of many other blood group antigens in the decades that followed.[3,17]

BLOOD COAGULATION, PRESERVATION, AND STORAGE

Despite some successes by Blundell and contemporaries, transfusions often failed to save lives, and remained a rarity until the early 20th century. Clotting remained a significant problem. A variety of devices, involving valves, syringes, and tubing, were invented to facilitate the collection and infusion of blood from one individual to another, including two invented by Blundell—the "Gravitator" and the "Impellor." The impellor consisted of a double-walled funnel in which

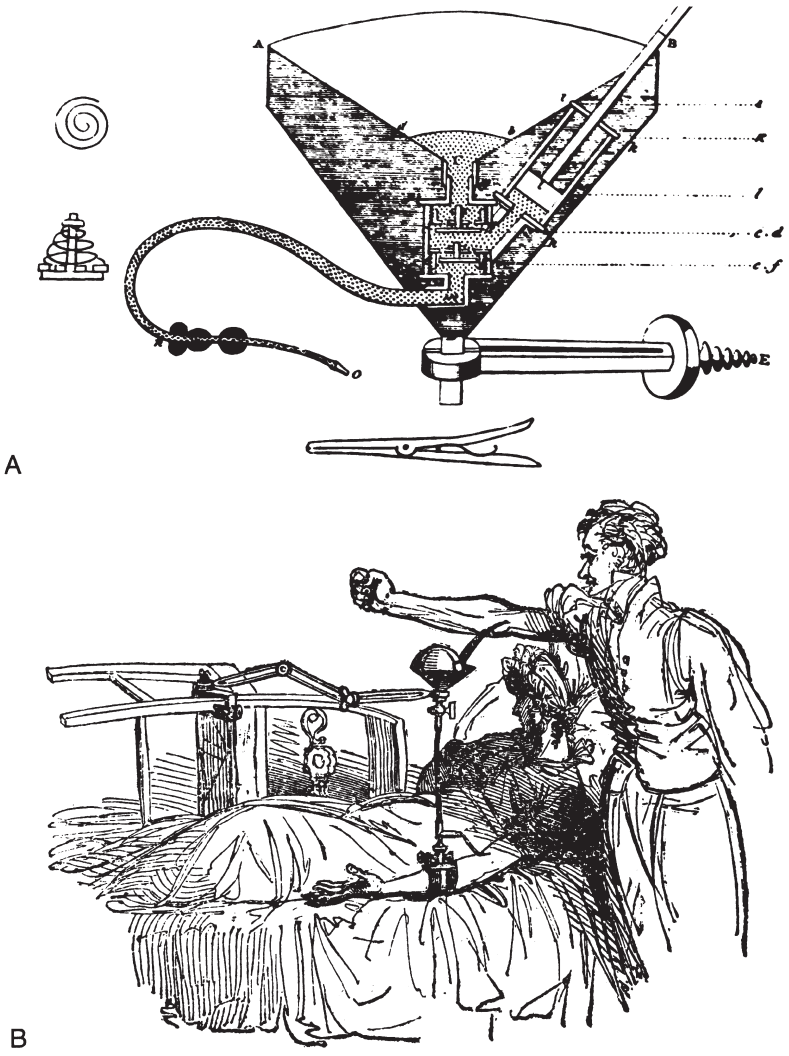

Figure 1–2 A. Blundell's "impellor." (Modified from Jones HW, Mackmull G. The influence of James Blundell on the development of blood transfusion. Ann Med Hist 1928;10:242.) **B,** Sketch of Blundell's gravitator. (Modified from Blundell J. Observations on transfusion of blood. Lancet 1828;2:321.)

the outer compartment was filled with warm water. The donor blood flowed into the funnel, was sucked into a syringe, and was forced along tubing into a cannula inserted into the patient's vein by means of two oppositely acting spring valves below the funnel[8] (Fig. 1–2). Gesellius used an equally complex device, in which the donor's back was lanced multiple times and capillary blood extracted using suction cups[5,8] (Fig. 1–3). James Aveling used a simpler method for direct blood transfusion from a donor using two silver cannulae, inserted into the recipient and donor, and connected by rubber tubing with a compressible bulb in the middle to promote and sustain flow.[11] The Aveling device is featured in the first known photograph of an actual blood transfusion, taken at Bellevue Hospital in New York City in the 1870s[9] (Fig. 1–4). In 1908, Alexis Carrel, a French researcher working at the Rockefeller Institute for Medical Research in New York, perfected a surgical technique for the direct anastomosis of donor artery to recipient vein.[3] Although highly effective at providing blood to the patient without clotting, performance of this technique required tremendous skill. Further, it required donors willing to undergo the painful procedure. It was also impossible to accurately estimate the amount of blood passed from donor to recipient; donors often became hypotensive or recipients developed circulatory overload.[3]

CITRATE ANTICOAGULATION

A chemical approach to anticoagulation was first attempted by Braxton Hicks, a 19th-century obstetrician, who experimented with phosphate of soda. Unfortunately, none of the four patients in whom it was used survived.[8] Other substances used in anticoagulation attempts included sodium bicarbonate, ammonium oxalate, arsphenamine, sodium iodide, sodium sulfate, and hirudin.[8] Surprisingly, these initial attempts did not include sodium citrate, which had long been used in laboratories as an anticoagulant.[8] The 1% concentration of citrate commonly used in the laboratory, however, was toxic to humans.[3] Nonetheless, in 1914 Albert Hustin reported the first human transfusion using citrated blood.[8] In 1915, Richard Lewisohn of the Mount Sinai Hospital in New York proved that a 0.2% sodium citrate solution was effective as an anticoagulant for blood, while having no toxicity even when as much as 2500 mL of citrated blood were transfused.[3] Also in 1915, Richard Weil, an American pathologist, found that citrated blood could be refrigerated for several days before use.[18] Lewinsohn and Weil, as well as Rous and Turner, found that addition of dextrose to citrate would preserve blood for up to 2 weeks[1,5] (Fig. 1–5). This permitted the first transfusion of stored blood in WWI by an American army physician, Oswald Robertson,

who transfused 20 casualties on 22 occasions during the battle of Cambrai in November 1917. Nine of the 20 recipients lived.[19] The primary disadvantages of the Rous-Turner solution were that it was difficult to prepare and required a large volume of preservative solution in relation to the amount of blood. However, it remained the only anticoagulant–preservative solution available through most of WWII.[5] Acid citrate dextrose (ACD), developed in 1943 by Loutit and Mollison, allowed for blood to be stored for up to 3 to 4 weeks,[20] could be autoclaved, and had the advantage of being easier to prepare,

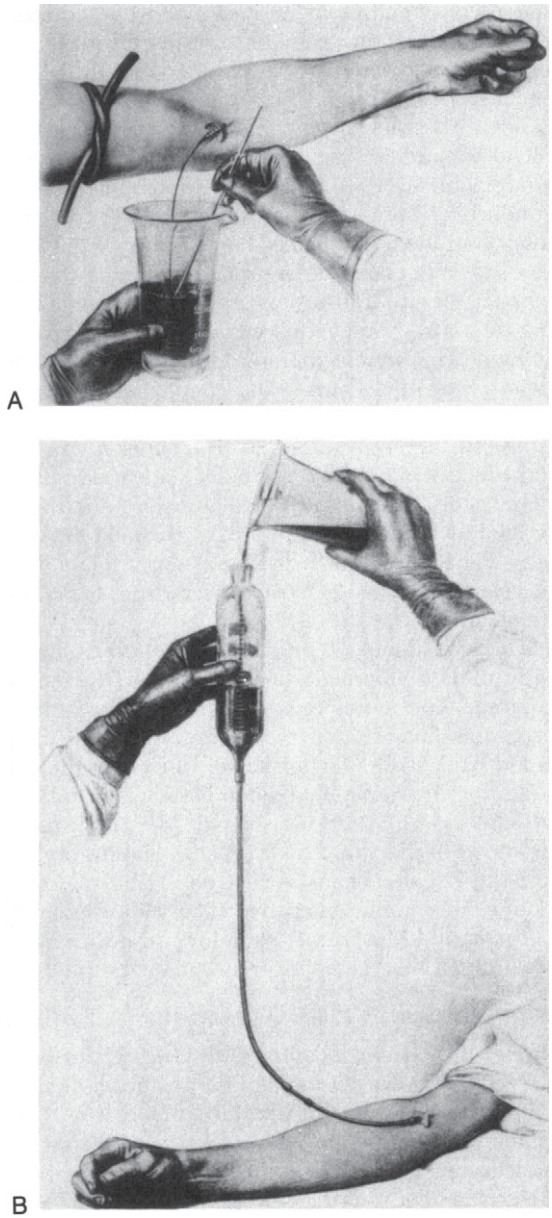

Figure 1–5 Lewisohn's method of transfusion of citrated blood. Blood is collected in a graduated flask (**A**) and is promptly transfused to the patient (**B**). (Modified from Lewisohn R: The citrate method of blood transfusion after ten years. Boston Med Surg J 1924;190:733.)

while requiring a smaller volume of solution relative to the amount of blood. Citrate phosphate dextrose (CPD) solution was subsequently adopted after studies showed blood could be stored for up to 28 days with better red cell survival than ACD.[3,21] Long-term red cell preservation by freezing began in 1950, when Smith and colleagues showed that glycerol could prevent freeze–thaw damage.[22]

ADVENT OF BLOOD BANKS

The first blood donor service was established in 1921 by Percy Oliver, Secretary of the Camberwell Division of the British Red Cross.[3] At this time, donors generally came from an unreliable supply; most from the patient's family and friends, or from indigents. Sometimes, no compatible donor could be found. On one such occasion, Oliver was contacted

by a hospital with an urgent request for blood. Oliver and his coworkers rushed to the hospital to see if they could help. Blood from one individual in the group, a nurse, was found to be compatible with the patient. This experience gave Oliver the idea to create a stable supply of potential blood donors. In the program he developed, each potential blood donor underwent a physical examination, blood typing, and testing for syphilis before placement on the volunteer list. Because many physicians were still reluctant to use anticoagulation, the volunteer would go to the hospital and provide direct donation via venous cutdown (rendering the vein useless for subsequent donations). The service was supported entirely by donations, and the services were provided free. In 1922, the donor list consisted of 20 volunteers whose services were requested 13 times. By 1925, the number of requests had risen to 428, and it doubled the following year.[3,7] The increasing demand ultimately led to establishment of a new organization, the Greater London Red Cross Blood Transfusion Service.[7]

The first true predecessor to the modern blood bank was established in 1935 at the Mayo Clinic.[23] Others credit the first blood bank to Bernard Fantus, who established a blood bank at Cook County Hospital in Chicago in 1937.[24] In this latter facility, blood was collected into glass flasks containing sodium citrate, sealed, and stored refrigerated. Pilot tubes were prepared for typing and serology testing. Fantus was the first to coin the phrase "blood bank" for the operation because blood could be stored and saved for future use.[24] During the Spanish Civil War (1936–1939), Federico Duran-Jorda organized a highly successful mobile blood bank that could be transported wherever needed. Every donor was assessed with a questionnaire, physical examination, syphilis testing, and testing for blood type and red cell concentration. Only universal type O blood was collected. Using an entirely closed system of his own design, Duran-Jorda collected the blood into glass bottles containing a citrate and glucose solution.[7,25] Blood was then transported to front-line hospitals in vehicles fitted with refrigerators.[26] At the height of fighting, Duran-Jorda's blood center in Barcelona was processing up to 75 blood donations per hour.[7] When it became evident that the Nationalists would win the war, Duran-Jorda left Spain for England, where he assisted Janet Vaughan in establishing a blood bank at Hammersmith Hospital in 1938. Because war with Germany was imminent, the Medical Research Council supported Vaughan's proposal to establish four blood depots in London. In 1938, the War Office also created the army blood supply depot under the control of Lionel Whitby.[3] The Army's policy, to supply blood group O red cells at the battlefronts with blood that had been collected centrally rather than collected at the front from troops, proved to be highly successful.[3]

TRANSFUSION IN WWII

Beginning in September 1940, London was relentlessly assaulted for months by nightly German bombs that caused tens of thousands of deaths and injuries. The efficient organization of the blood depots provided for rapid transfusion of the wounded. Through experience, it became clear that blood transfusion could be used to treat injuries other than hemorrhage, including traumatic shock, crush injuries, fractures, and burns, creating a need for an even greater blood supply than could be provided by Britain alone. Americans were eager to help, but knew that whole blood could not survive the long transatlantic journey.[7]

Use of Plasma

John Elliott, laboratory chief at Rowan Hospital in North Carolina, had been experimenting with methods of separating plasma from blood when a patient who had been stabbed in the heart presented at the emergency room. Because there was no time to obtain a blood sample for type and crossmatching, Elliott decided to try transfusing the patient with the plasma he had in the laboratory. The patient survived. Elliott found that, in addition to having many of the beneficial properties of whole blood transfusion, plasma retained its usefulness for months. He was convinced that plasma could be the best transfusion liquid available and became a relentless advocate for its widespread transfusion.[7] Elliott's campaign efforts were successful. In August 1940, the Americans launched the Plasma for Britain program, headed by Charles Drew (Fig. 1–6). Drew was an African American surgeon whose 1938 doctoral thesis, "Banked Blood," was considered the most authoritative work on the science of blood storage at the time.[27] Under Drew's directorship, the Plasma for Britain program was a tremendous success, collecting blood from nearly 15,000 people, which produced 5500 vials of plasma (Fig. 1–7). Drew's contribution, however, extended beyond the sheer number of units collected. He was said to be the first to develop and implement strict procedures for blood collection and testing on a large, "industrial" scale.[7] In 1941, Drew was appointed director of the first American Red Cross Blood Bank, in charge of blood for use by the U.S. Army and Navy. In 1942, however, he resigned his official posts following the armed forces' decision that the blood of African Americans would be accepted but would have to be stored separately from that of whites.[7,27]

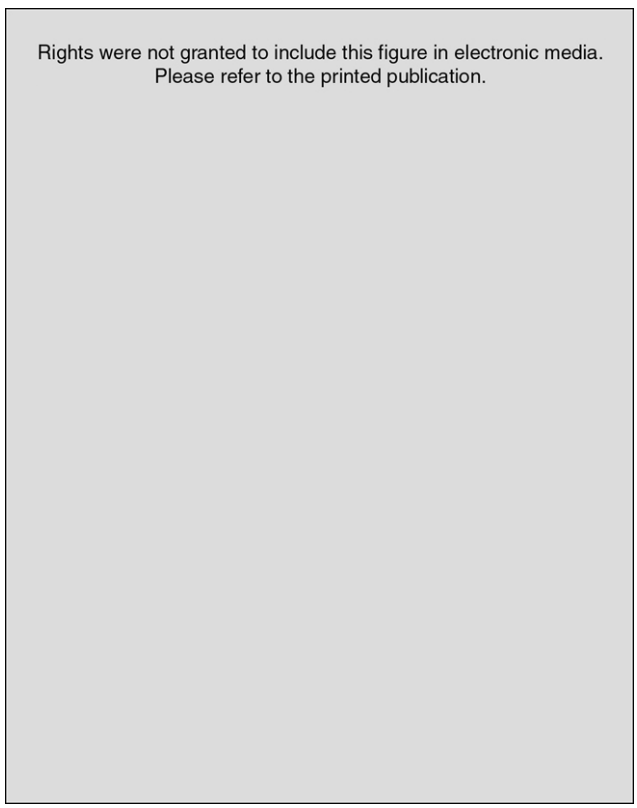

Figure 1–6 Dr. Charles Drew. (From Star D. Blood. An epic history of medicine and commerce. New York, HarperCollins Publishers, 2002.)

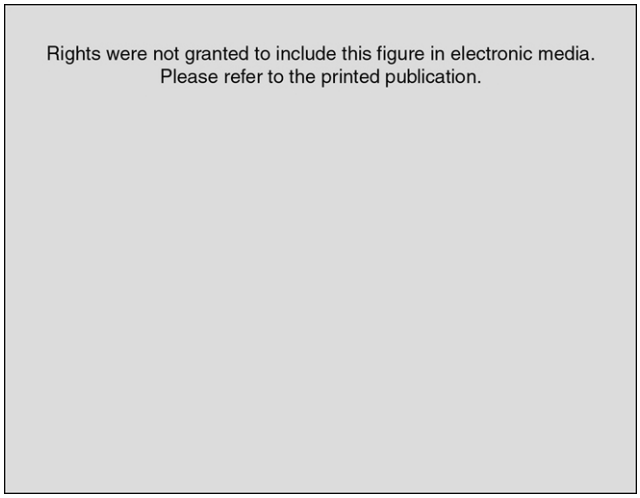

Figure 1–7 An American medic administers plasma to a wounded soldier in Sicily. (From Star D. Blood. An epic history of medicine and commerce. New York, HarperCollins Publishers, 2002.)

Eleanor Roosevelt took over his position. Drew became a professor of surgery at Howard University and trained numerous black surgeons. He died in an automobile accident in the late 1950s. It was widely alleged he didn't receive blood, because no "black blood" was available. This canard, however, is simply not true. Drew was transfused appropriately, but died as a result of injuries to his great vessels and his heart.[28]

Blood Fractionation

The benefits of plasma for treatment of injuries during WWII were evident, but like whole blood, plasma had its limitations. The protein-rich solution was highly prone to bacterial contamination. Freeze-dried plasma circumvented this problem, but was cumbersome and awkward to use on the battlefield. In 1940, Edwin Cohn, a Harvard chemist, isolated various fractions of plasma. Fraction V was found to be composed of albumin, which, in limited clinical studies of volunteers and accident victims, was found to restore circulatory collapse. Professor I. S. Ravdin at the University of Pennsylvania established albumin's efficacy following the bombing of Pearl Harbor in 1942, where albumin was used to treat injuries of 87 patients.[7] Most of these patients showed some clinical improvement, and only four suffered minor reactions.[3] Based on this success, the U.S. military added albumin production to efforts to produce plasma on a large scale.[7] Albumin had a number of advantages over plasma. Because of the method of production, cold ethanol precipitation/fractionation, albumin is free of bacteria. In addition, because albumin is highly concentrated, it could be transported in small vials easily on the battlefield. However, production of a single unit of albumin required pooling of multiple blood donations, and, like plasma, production of albumin was difficult. During WWII, both plasma and albumin were produced in vast amounts. By the end of 1943, over 2.5 million packages of dried plasma and nearly 125,000 units of albumin had been sent to the U.S. military.[7]

Cohn's fractionation of plasma yielded numerous benefits beyond the purification of albumin. Fraction I was found to contain fibrinogen; fractions II and III contained immunoglobulins that proved effective in the temporary prevention of a variety of infectious diseases, including infectious hepatitis (hepatitis A), rubella, and measles, and in the treatment of hypogammaglobulinemia.[16] Of particular significance, the isolation of Rh antibodies paved the way for discovery of methods to prevent most severe cases of hemolytic disease of the fetus and newborn.

IMMUNOGLOBULIN IN THE PREVENTION OF RH-HEMOLYTIC DISEASE OF THE FETUS AND NEWBORN

The first major advance, following Levine's discovery that maternal Rh antibodies were the cause of erythroblastosis fetalis, was the development of a practical procedure for umbilical vein exchange transfusion by a Boston pediatrician, Louis Diamond, in 1947. However, it took another 20 years before a treatment to prevent hemolytic disease of the newborn was discovered.[3] Initial experiments by Stern and colleagues in 1961 showed that passively administered "incomplete" anti-Rh antibody could interfere with primary Rh immunization.[16,29,30] Because immunoglobulin M (IgM) antibodies would not cross the placenta, investigators initially attempted to use "complete" or IgM anti-Rh antibody to block Rh immunization in Rh-negative males, but found that antibody formation was enhanced rather than suppressed.[31] Subsequently, suppression of Rh immunization by "incomplete" IgG anti-Rh antibody was demonstrated by Clarke and coworkers[30,31] and Freda and coworkers,[32,33] who were the first to use an immunoglobulin concentrate of IgG anti-Rh antibody given intramuscularly. Shortly afterward, it was realized that transplacental hemorrhage occurred chiefly at the time of delivery, and both groups showed that anti-Rh antibody given soon after delivery would suppress Rh immunization.[16,34,35]

BLOOD COMPONENTS

Another advance in transfusion was development of the first cell separator in 1951 by Edwin Cohn; the cell separator allowed blood to be separated into red cells, white cells, platelets, and plasma. Although in principle it was possible to harvest any particular component of the blood, in practice, satisfactory yields of only red cells or plasma could be obtained.[16]

Cohn's cell separator paved the way for component therapy, but the development of plastic containers made modern component therapy possible. Up until the 1950s, blood was collected through steel needles and rubber tubing into glass, rubber-stoppered bottles, which were reused following washing and sterilization.[1] Pyrogenic reactions and air embolism were known risks to blood collected using these materials. In 1952, Carl Walter, a researcher under Harvey Cushing, and William Murphy described a system in which the blood was collected into a collapsible bag of polyvinyl resin.[1,36] Plastic had the flexibility to permit the removal of plasma following sedimentation or centrifugation, techniques that became the foundations for component production.[1,37]

FACTOR VIII CONCENTRATES

The ability to separate blood into components resulted in major advances for the treatment of hemophilia. Initially, hemophiliacs were treated with fresh frozen plasma; however,

massive volumes were required to replenish the deficient factor VIII in these patients. A more concentrated form of the required factor VIII was found in the cryoprecipitated portion of plasma by Judith Pool in 1965.[38] In 1968 Brinkhous and Shanbrom produced concentrated factor VIII by pooling hundreds to thousands of units of plasma. These factor concentrates could be carried by the patient and administered by self-injection at the earliest sign of bleeding.[7,39] Factor VIII concentrates were a major advance in the treatment of hemophilia A, but they came with a very high risk of infectious disease transmission, first with hepatitis and later with human immunodeficiency virus (HIV).

INFECTIOUS DISEASE TRANSMISSION

The first hint that hepatitis could be caused by blood transfusion came during WWII following administration of yellow fever vaccines produced using human serum as a stabilizer.[1] This was followed by a report in 1943 of a series of seven cases of jaundice following transfusion of whole blood or plasma.[40] At the time, serum hepatitis (or hepatitis B) was assumed to be the major cause of transfusion-associated hepatitis. This began the awareness that blood transfusion could transmit potentially deadly viral diseases. In 1962, the connection between paying for units and an increased risk of post-transfusion hepatitis was made by J. Garrett Allen, a Stanford surgeon[41]; however, it wasn't until a decade later that the National Blood Policy mandated a voluntary (unpaid) donation system in the United States.[1] Subsequently, in 1975 transfusion-associated hepatitis was shown to be primarily due to non-A, non-B hepatitis, or what became identified later as hepatitis C.[42] Despite the risk of hepatitis transmission, blood utilization continued to increase. In the United States, for example, blood utilization doubled between 1971 and 1980.[1] However, the emergence of acquired immunodeficiency syndrome (AIDS) changed this trend.

The first case of AIDS was reported in 1981. This mysterious disease initially occurred only in gay men. However, within a few years, it became clear that AIDS was caused by a blood-borne virus. The first reported case of transfusion-associated AIDS occurred in a 20-month-old infant who had received multiple transfusions for hemolytic disease of the newborn.[43] Hemophiliacs, dependent on lifelong infusions of factor VIII concentrates, were particularly devastated by the disease. In 1985, the first serologic test to detect HIV was implemented by blood banks to protect the blood supply. However, the possibility that other, as yet unknown, pathogens could also be transmitted by blood transfusion resulted in a new awareness that blood should be used judiciously. Multiple serologic tests are now routinely employed on every blood component for a variety of infectious agents, including hepatitis B, hepatitis C, HIV, cytomegalovirus (CMV), syphilis, and human T-lymphotropic virus (HTLV). Despite the improvement in blood safety that serologic testing provides, the risk of infectious disease transmission is not completely eradicated from the blood supply due to the window period in which donors are infectious, but have not yet developed detectable antibody. The development of nucleic acid amplification technology (NAT) has limited the risk of infectious disease transmission even more by allowing the direct detection of even small quantities of pathogen. Currently, NAT testing is widely employed for HIV and hepatitis C detection, and is used, in certain areas, for detection of hepatitis B virus and West Nile virus. Some type of pathogen inactivation applied to blood components might obviate the need for yet more testing of known and unknown pathogens that might be transfusion-transmissible.

NONINFECTIOUS COMPLICATIONS OF TRANSFUSION

In addition to infectious diseases, other risks of transfusion became apparent as transfusions increased. Transfused leukocytes were found to have a number of undesirable effects (e.g., graft-versus-host disease [GVHD] and febrile reactions).[8] In 1970, Graw and colleagues demonstrated that GVHD could be prevented by the irradiation of blood components.[44] In 1962, the first-generation leukocyte filter was shown to be effective in the prevention of febrile transfusion reactions.[45] The additional benefits of leukoreduction, including reduction of leukotropic viruses, such as HTLV 1/2 and CMV, and minimization of the risk of human leukocyte antigen (HLA) sensitization, have resulted in the widespread adoption of leukoreduction of cellular blood components.

THE MODERN ERA

Transfusion medicine continues to evolve in the modern era. New, problematic infectious agents emerge, such as West Nile virus, which is usually transmitted to humans by mosquitoes. West Nile virus was first reported to be transmitted by transfusion and organ transplantation in 2002.

As detection and prevention of transfusion-transmitted viral infections has improved, bacterial contamination has evolved into one of the most significant causes of transfusion-transmitted infectious disease. Bacterial detection systems are being used on platelet components with some success. Fortunately, new methodologies designed to inactivate bacteria have been developed and are undergoing evaluation.[46]

Alternatives to human blood for transfusion, so called "blood substitutes," continue to be actively investigated but have thus far had limited success. Current "blood substitutes" are limited to substances designed to carry oxygen. Unfortunately, these substances have limited application and are associated with a unique set of risks and potential complications.[47]

The history of transfusion medicine parallels mankind's understanding of physiology, immunology, chemistry, infectious diseases, and advances in technology. What began as a belief that blood carries important healing properties has been validated by science. However, despite numerous advances over the centuries, blood remains an indispensable, life-giving force. Interestingly, some of the more important advances in blood banking/transfusion medicine have occurred as the result of wars.

SUMMARY REMARKS

Blood transfusions today are an indispensable part of many medical and surgical therapies. The use of blood and its components temporarily replaces what may be lost or not produced before, during, or after a disease process and/or its treatment. The benefits of transfusion today far outweigh

their minute (yet real) risks with all the current safeguards to select donors, test blood, and ensure that compatible blood is transfused to the correct patient. Transfusion medicine has come a long way due to multiple pathfinders, adventurous physicians, and courageous donors and patients, especially in the last half century. We owe much to these pioneers.

A. Immunohematology

i. Basic Principles

Chapter 2

Principles of the Immune System Central to Transfusion Medicine

Terrence L. Geiger

INTRODUCTION

The histories of immunology and transfusion medicine intertwine, and efforts in each field have revealed fundamental truths about the other. One of the early leaders in both areas was Paul Ehrlich.[1,2] At the turn of the 19th century, Ehrlich observed that goats were able to produce an immune substance—antibodies—which could destroy red blood cells (RBCs) derived from other goats. Interestingly this substance did not affect a goat's own RBCs. From these findings Ehrlich developed the concept of *horror autotoxicus,* that in order to avoid "autotoxicity," or self-harm, immune responses are directed against foreign and not self compounds. Karl Landsteiner expanded on Ehrlich's work.[3] He demonstrated that anti-red cell agglutinins found in human serum, as in goats, were never directed against self, or autologous, RBCs. However, he also observed that some serum specimens were able to agglutinate samples of homologous RBCs, while other serum specimens could not. He categorized these agglutinins in analyses that led to the description of the ABO blood group system and thereby formed a scientific basis for modern transfusion medicine.

One hundred years after the pioneering studies of Ehrlich and Landsteiner, we still struggle to understand the immune mechanisms they described. The human immune system, functioning as a barrier against pathogen attack, can prevent the transfusion of cells and proteins and the transplantation of tissues. These cells and tissues, which are foreign to our bodies, contain antigens, or chemical structures recognized by the immune system. As Ehrlich observed, our immune system generally does not respond to self-antigens, antigens that are intrinsic to our bodies. In contrast, it can and often will respond against foreign antigens. In the case of transfusion, these foreign antigens result from differences between the structures of proteins and sugars present in transfused blood and those native to the recipient.

The recognition of antigens within transfused blood by the immune system may have several consequences. It may lead to the destruction of transfused cells and the neutralization of transfused proteins. This can occur through the generation of specific antibodies or less frequently through the activation of cellular immunity. Immune engagement may also inactivate the immune system. This is called *immune tolerance.* If tolerance develops against antigens on transfused or transplanted cells, the immune system will not respond when it encounters the same antigens again, even if they are present on different cells or tissues. Finally, the immune system may neither elaborate an effective response against an antigen nor become tolerant of it, an event sometimes called *immune ignorance.*[4,5] In each of these circumstances a transfusion is not passively witnessed by the immune system. Whether or not we observe a clinical consequence of immune engagement after a transfusion, the immune system is continuously active, identifying antigens and determining whether and how to respond.

The immune system consists of two lines of defense. The first, termed the *innate immune response,* is triggered by substances common to many pathogens, such as bacterial lipopolysaccharide or viral nucleic acid. These substances indicate potential danger to a host. Innate immunity is immediate. It is found in most multicellular organisms, even those with very short life spans, and it rapidly neutralizes the offending agent. A second, more complex immune response may follow the innate response. This response, which specifically targets antigens present in the immunizing substance, is called the *adaptive immune response.* Adaptive immunity requires days to weeks to develop and is only found in complex organisms. It is characterized by the development of antigen-specific antibody and T-cell responses.

THE INNATE IMMUNE SYSTEM

The innate immune system includes an amalgamation of interacting pathways that use invariant proteins to protect our bodies from specific types of assault. It continuously monitors our internal environment for the presence of pathogens and other hazards. It also defines the type of danger present, initiates a protective response, and establishes an environment conducive to the formation of effective adaptive immunity.[6]

The innate immune system includes dedicated cell types that lack antigen-specific receptors yet are able to recognize and neutralize pathogens and infected cells. These cells can destroy pathogens through phagocytosis, or ingestion, or through the production of cytocidal compounds such as reactive oxygen species and nitric oxide. They can also sound an alarm, recruiting other inflammatory cells to sites of infection and initiating inflammatory reactions. Examples of innate immune cells include macrophages, mast cells, neutrophils, eosinophils, and natural killer (NK) cells.

Innate immunity is, however, not limited to specific cell types. Elements of innate immunity are present in and around virtually all cells in our body. Some of these elements are produced within our cells, such as the cytoplasmic antiviral proteins that are produced in response to viral infections. Others, such as secreted antimicrobial peptides called *defensins* and *cathelicidins,* are exclusively extracellular.[7]

Activation of innate immunity begins with the recognition of pathogen motifs by specific receptors.[8] These motifs tend to be conserved within a class of organisms. An example is gram-negative bacteria, whose double membrane contains endotoxin, a unique complex of lipid and polysaccharide also called *lipopolysaccharide* (LPS). LPS binds to an LPS-specific receptor present on innate immune cells called *Toll-like receptor 4* (Tlr4).[9] Tlr4 is one of a group of similar receptors that are expressed on the cell surface or in endosomes (internalization vacuoles) and signal when danger is present.[10] Other Toll-like receptors recognize motifs specific to gram-positive bacteria, viruses, or other pathogens (Table 2–1).

When a Toll-like receptor is activated, it induces signaling molecules that coordinate the early response against an offending pathogen. These signaling molecules are called *biological response modifiers* (BRMs). BRMs include lipids, such as leukotrienes, and other small signaling molecules, such as histamine and serotonin. They also include a group of messenger proteins called *cytokines* that are critical in orchestrating the innate immune response (Table 2–2). There are several classes of cytokines with distinct roles in innate immunity. The interaction of viral DNA or RNA with specific Toll-like receptors induces the synthesis of Type I interferons (IFNs), a class of cytokines that binds IFN receptors on cells and promotes the formation of proteins that block virus replication. Another class of cytokines is called chemokines. The word *chemokine* is a conjunction of chemotactic, the promotion of migration along a chemical gradient, and cytokine. As chemokines diffuse from their site of production, they form a gradient along which immune cells migrate. An example is interleukin-8 (IL-8), which recruits inflammatory cells to the site of an infection.[11,12] Other released cytokines promote inflammation. For example, tumor necrosis factor (TNF) activates endothelial cells, aiding in the diapedesis of reactive cells into tissue, and increases the production of pathogen-neutralizing effector molecules such as reactive oxygen species and nitric oxide.[13] Yet other cytokines, such as IL-12, primarily link innate and adptive immunity. IL-12 promotes T-lymphocyte differentiation into helper T cells (Th1 cells) capable of recruiting and activating macrophages that destroy pathogens.[14] Cumulatively, the cytokines and other BRMs released during the innate immune response form a communication network between cells that identifies the pathogen class and severity of the infection and establishes an initial response to it.

Table 2–1 Recognition of Pathogen-Specific Motifs by Toll-like Receptors

Receptor	Recognition Motif	Pathogen
Tlr1 (associates with Tlr2)	Triacyl lipoproteins	Gram-negative bacteria
Tlr2	Peptidoglycan, lipoproteins, lipopeptides	Gram-positive and other bacteria, parasites, fungi
Tlr3	Double-stranded RNA	Viruses
Tlr4	Lipopolysaccharide	Gram-negative bacteria
Tlr5	Flagellin	Bacteria
Tlr6 (associates with Tlr2)	Diacetylated lipoproteins	Mycobacteria
Tlr7	Viral single-stranded RNA; imidazoquinalines and other guanosine nucleotide-related synthetic compounds	Viruses; synthetic agents
Tlr8	Viral single-stranded RNA	Viruses
Tlr9	Unmethylated CpG DNA	DNA viruses, prokaryotes

Table 2–2 Some Important Cytokines and Their Functions

Cytokine	Function
IL-1	T-cell and APC stimulatory, fever
IL-2	T-cell expansion and apoptosis sensitivity
IL-4	B-cell stimulation, IgE production, Th2 differentiation
IL-5	Eosinophil expansion and development
IL-10	Suppression of macrophage and DC function
IL-12	Th1 differentiation, NK activation
IL-15	NK cell and T-cell expansion and survival
IFN-γ	Macrophage activation, enhancement of antigen presentation, promotion of IL-12 production
IFN-α, β	Antiviral
TNF-α	Inflammation, sepsis
TGF-β	Anti-inflammatory, T-cell inhibition, IgA production

Although critical for innate immune pathogen detection, Toll-like receptors are not exclusive in this ability. Other proteins have complementary functions.[15] A cytoplasmic protein called *retinoic acid inducible gene 1* binds viral RNA and induces production of IFN-α and IFN-β. Other proteins that include nucleotide-binding oligomerization domains have been found to recognize intracellular bacteria. Mannose-binding lectins in the extracellular fluid bind the surfaces of pathogens and then activate complement. Recent data have also documented a completely new manner through which our bodies can recognize pathogens. Very short RNA sequences, microRNAs, are able to specifically recognize viral genetic material and in so doing inhibit viral replication within a cell.[16] Our ability to withstand the onslaught of potential invaders surrounding us is critical to our survival, and our bodies invest heavily in our innate immune system as a first line of defense.

The activation of innate immunity through pathogen-specific receptors may seem irrelevant to immune responses to blood transfusions, which to the best of our abilities lack contaminating pathogens. However, the innate immune system establishes a basal inflammatory state. Transfused RBC or plasma antigens are presented to the adaptive immune system in the context of this state, which may influence the immune response to them. Although a direct link between a specific type of inflammatory response and the type of response generated against transfused allogeneic blood products has not been demonstrated, associations between infection and other alloimmune responses, particularly graft rejection, have been documented.[17,18] Furthermore, specific immune reactivity against "bystander" antigens during responses against pathogens has been described in other circumstances and is therefore likely present in the context of transfusion.[19–21] Indeed, establishing such a bystander response forms the scientific rationale for the adjuvants present in modern vaccines. Adjuvants, by stimulating specific innate immune receptors, influence the magnitude and quality of the adaptive immune response against co-administered antigens.[22] Thus, the innate immune context in which a transfusion is administered may have a significant effect on the immunologic outcome of that transfusion.

THE ADAPTIVE IMMUNE SYSTEM

The adaptive immune system selectively neutralizes pathogens and nonpathogenic foreign antigens. It recognizes these through specific antigen receptors. Whereas receptors of the innate immune system detect just a handful of pathogen-specific chemical motifs, antigen receptors of the adaptive immune system are able to selectively identify billions of distinct antigenic structures. The 3 billion base pair long human genome would be insufficient to encode adequate numbers of proteins to accomplish this feat if each receptor was a separate gene, as is the case for Toll-like receptors. To circumvent this problem, antigen receptors are built up from modules that allow the incorporation of variability as they form (Fig. 2–1).[23] Each polypeptide of an antigen receptor is composed of three or four fragments of DNA. These fragments are called variable (V), diversity (D), junctional (J), and constant (C) fragments. More than a single piece of DNA can encode for each of these fragments, and their arbitrary linkage results in combinatorial variation. For example, if an organism has 20 V regions, 2 D regions, 10 J regions, and 1 C region for a receptor in its genome, random recombination would allow the formation of 20×2×10×1 or 400 unique receptors from the 20+2+10+1, or 33, gene segments.

Two additional features promote variation. As the receptor fragments recombine, enzymes randomly insert or remove nucleotides at the recombination sites. The sites where these alterations are made correspond to parts of the receptor that directly contact antigen and are called *hypervariable regions*.[24]

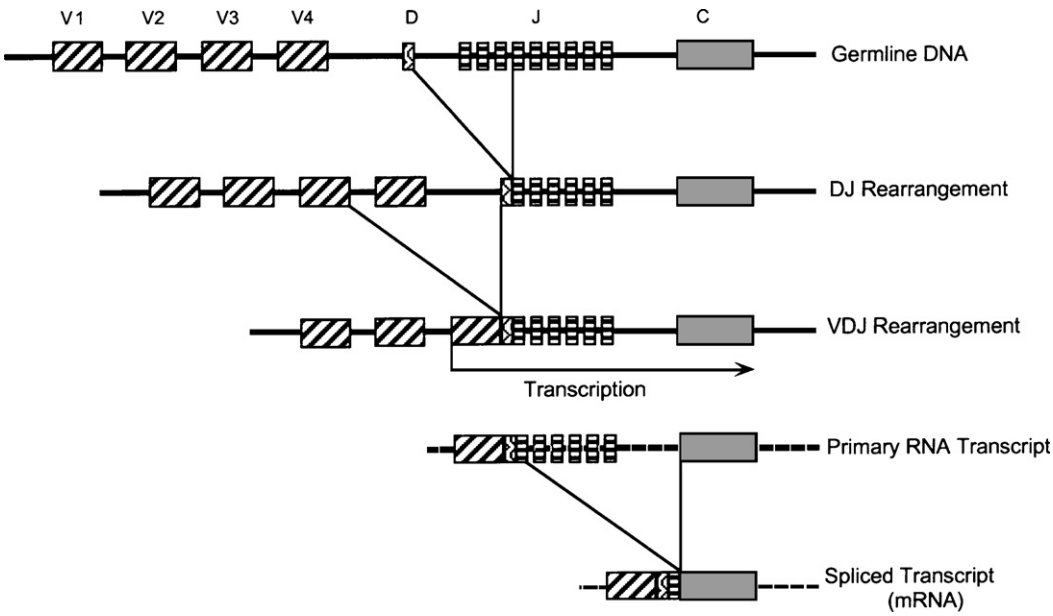

Figure 2–1 Antigen receptor gene rearrangement. The germline genetic sequence consists of multiple variable (V), diversity (D), and junctional (J) segments. Rearrangement of a D and J segment with excision of intervening DNA sequence is followed by that of the DJ sequence to a V region. Completion of rearrangement juxtaposes sequences necessary for RNA transcription. The RNA transcript is spliced to create an mRNA that is translated into an antigen receptor chain. The diagram is illustrative and does not indicate the full complexity of the T-cell receptor or B-cell receptor loci.

Thus antigen receptors are most variable at critical antigen-binding sites. Further, antigen receptors are heterodimers composed of two polypeptides, a V-D-J-C chain, and a V-D-J chain. Each of these receptor components uses an independent set of V, D, J, and C fragments. The chains recombine independently but recognize antigen together. Thus billions of distinct antigen receptors may form from a relatively small number of gene fragments.

Antigen receptors are expressed on only two classes of cells, B lymphocytes and T lymphocytes. On B cells they form the B-cell receptor (BCR), which is a cell surface form of immunoglobulin. On T cells they form the T-cell receptor (TCR). Each T cell or B cell expresses only a single (or in some rare cases two) immune receptors on their cell surface.[25] Therefore, each T cell or B cell is essentially a clone recognizing a distinct piece of an antigen, called an *epitope*. Because of the diversity of immune receptors, the frequency of T cells or B cells able to respond to any single antigenic protein is extremely low, typically ranging from 1/10,000 to 1/100,000 cells.[26] Receptor engagement activates a lymphocyte and may lead to the selection and rapid outgrowth of rare antigen-specific clones. Cell activation by antigen may also induce differentiation into effector lymphocyte forms designed to participate in distinct types of immune responses, such as allergic responses or delayed type hypersensitivity responses.

The Trail of Antigen

Foreign antigens can enter the body through different routes. In the case of infection, entry is generally through the skin or mucosal tissues. In the case of transfusion, direct intravenous inoculation occurs. In both situations, antigens make their way to lymphoid tissue. Antigens in the skin are picked up by specialized resident skin dendritic cells called *Langerhans cells* and are then carried to draining lymph nodes.[27] Antigens in the blood are picked up by cells in the spleen. Antigens in the gut are taken up by cells in the gut-associated lymphoid tissue.[28] They are then presented to T lymphocytes and B lymphocytes by specialized antigen-presenting cells (APCs), also called *professional APCs*, in the lymphoid tissues. The lymphoid tissues are specifically designed to facilitate the interaction between rare antigen-specific T cells and B cells and APCs bearing their cognate antigen (Fig. 2–2).

The cell carrying antigen to lymphoid tissue may transfer that antigen to professional APCs within that tissue.[27] Alternatively the courier cell, often a resident tissue dendritic cell, may serve as the APC within the lymphoid tissue, directly presenting antigen to lymphocytes. Conversion of such courier cells to effective professional APCs requires their maturation under the influence of cytokines or Toll-like receptor signals that are present in the context of inflammation and innate immune activation. These stimuli induce the formation of signaling molecules on the surface of the APC that can bind and activate lymphocyte receptors. They also induce the secretion of cytokines and other BRMs by the APCs.[29,30] Such supplemental, or costimulatory, signals can both modify and augment the signal received by a lymphocyte through its antigen receptor. In the presence of costimulatory signaling, a lymphocyte may become more fully activated, permitting its expansion and differentiation into an effector cell. In contrast, the absence of costimulatory signals indicates to a lymphocyte that antigen is not being presented in the context of inflammation or host danger. Signals through antigen receptor in this circumstance lead to incomplete stimulation that may promote the development of immune tolerance, sometimes through the death of the responding antigen-specific lymphocyte.[31,32] As self-derived antigens will tend not to be presented in the context of inflammation, this form of tolerance is one route through which the immune system rids itself of self-reactive lymphocytes that may cause autoimmunity.

Antigen Presentation to T Cells

The TCR is a complex that includes six different polypeptides, most commonly α, β, γ, δ, ε, and ζ (Fig. 2–3).[33,34] The α and β chains, which include recombined VJC and VDJC regions, respectively, are directly involved in antigen recognition. The remaining polypeptides do not recognize antigen but transmit signals into T cells after antigen engagement occurs. The γ, δ, and ε signaling chains are collectively referred to as the CD3 complex.

Figure 2–2 Schematic depiction of the structure of a lymph node (**A**) and an area of the splenic white pulp (**B**). Lymphocytes enter through the high endothelial venule (HEV) or central arteriole and then migrate to T- or B-rich areas where they may interact with antigen-presenting cells. T cells and B cells may also engage each other, often at the interface between the B- and T-cell zones of the spleen or lymph node. (From Mondino A, Khoruts A, Jenkins MK. The anatomy of T cell activation. Proc Natl Acad Sci USA 1996;93:2246.)

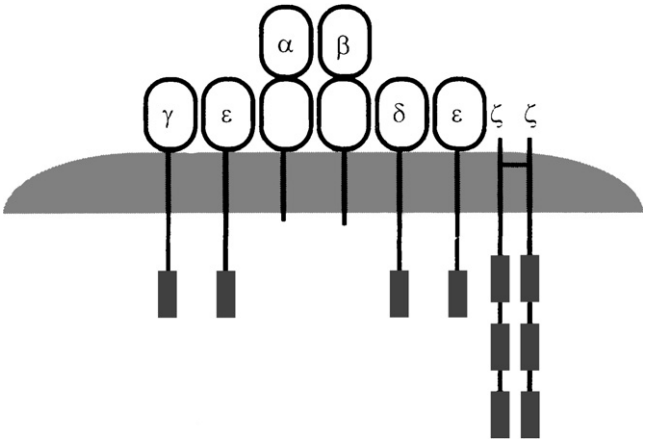

Figure 2–3 The TCR–CD3 complex consists of eight polypeptide chains. Specificity is determined by the αβ chains or, in some T cells, by analogous γδ TCR chains. Expression of the CD3 γ, δ, and ε chains, as well as ζ or its splice variants, are necessary for surface expression and signaling.

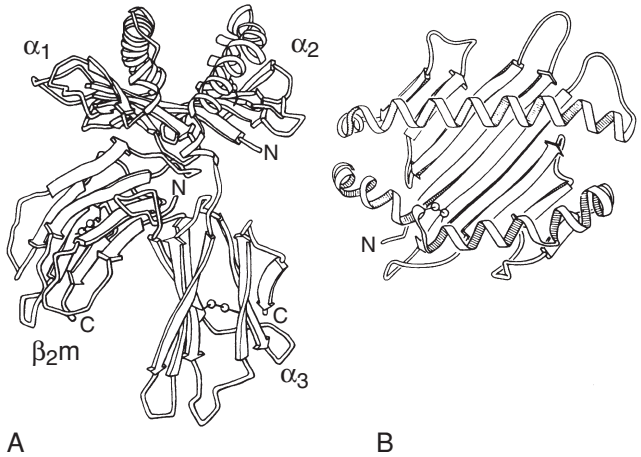

Figure 2–4 Structure of a class I MHC molecule. **A,** Three-dimensional ribbon model of the extracellular portion of the molecule. The peptide-binding groove lies between the helices at the top of the molecule. **B,** Top view. (From Bjorkman PJ et al Structure of the human class I histocompatability antigen, HLA-A2. Nature 1987;329:506.)

T cells do not see antigen alone through their TCR. They see it only in the context of major histocompatibility complex, or MHC, proteins. The significance of the MHC, also called the human leukocyte antigen (HLA) complex in humans, was first recognized through the work of Peter Gorer and George Snell in the 1930s.[2] Gorer and Snell were studying tumor graft rejection and determined that this genetic locus was absolutely critical in determining whether grafted cells were rejected. We now know that the MHC serves as a window through which T cells see the world around them. T lymphocytes recognize antigen only in the context of MHC molecules. Recognition is remarkably specific. Even subtle allelic variations in a single MHC molecule are sufficient to abrogate T-cell recognition.[35]

MHC proteins fall into two categories, class I and class II molecules.[36] Class I MHC molecules are heterodimers consisting of a larger α or "heavy" chain, which is membrane bound, and a smaller soluble protein called *β_2-microglobulin*. Class II MHC molecules are heterodimers of two membrane-bound polypeptides, an α chain and a β chain of roughly equal size. How the MHC presents antigen to T cells was not clear until the late 1980s when x-ray crystallographic structures of MHC molecules were solved (Fig. 2–4).[37–39] Although the amino acid sequences of class I and class II molecules are distinct, they form similar three-dimensional structures. The upper surface of the MHC molecule forms a platter, called a β *sheet*, on top of which lie two parallel tubular coils of peptide, called α *helices*. Between the α helices lies a groove into which various protein fragments, or peptides, may bind. These peptides, presented together with their restricting MHC molecules, are the antigenic structures recognized by T lymphocytes.

Class I MHC molecules bind peptides approximately 8 to 10 amino acids in length, whereas class II MHC molecules bind longer peptides, approximately 13 to 24 amino acids. Only a few interactions between peptide amino acids and the MHC are needed to stabilize binding.[40,41] This allows for the formation of large numbers of different peptide–MHC complexes. A typical antigenic protein will have one or more peptides able to bind any specific MHC molecule. The MHC therefore serves as a platform that displays the antigenic universe to T cells. The T cells view these peptides through their TCR, which recognize and bind the peptide–MHC complex.

It could be imagined that a pathogen may readily evade the immune system by simply designing proteins that do not contain MHC-binding motifs. However, this is not possible for two reasons. First, we express several different class I and class II MHC molecules, three of each for the major, or classical, MHC forms on each chromosome. These are called HLA-A, -B, and -C for the human class I locus, and HLA-DR, -DQ, and -DP for the class II locus. Therefore, an individual heterozygous for each locus may have a total of six different class I molecules, and, because the α and β chains of the class II molecule encoded on each chromosome may heterodimerize either in cis or in trans, an even larger number of distinct class II MHC molecules. If a pathogen's proteins failed to bind one HLA protein, it would likely bind one of the others. More importantly, the MHC genes are remarkable among all genes for their polymorphism, or allelic variability. Because of this variability, most of us have different sets of MHC genes. Indeed, no other human genetic locus is as polymorphic as the MHC.[42] Sequence variation of the allelic variants is particularly prominent at the peptide-binding groove, and different alleles of even a single MHC gene therefore often have distinct peptide-binding and antigen-presentation properties. MHC polymorphism ensures that a pathogen that attempted to evade the immune system of one individual would not be able to do so for others, thereby protecting the population as a whole.

The polymorphism and polygenicity of the MHC also presents a problem in transfusion and transplantation. T lymphocytes respond particularly vigorously against allogeneic (allelically distinct) MHC molecules. Each of these allogeneic MHC molecules can bind thousands of different peptides. Peptides derived from self-antigens, to which a person's immune system is normally tolerant, when combined with allogeneic MHC molecules, form complexes that are foreign to the host immune system.[43] It is estimated that roughly 1% to 10% of a person's T cells will respond to another person's allogeneic MHC combined with the array of self-peptides that may bind in its groove. For stem cell transplant recipients, this recognition may be manifested by the development of graft-versus-host disease (GVHD) or graft rejection. In the case of transfusion, it may be made apparent by the development of immune responses resulting in transfusion-associated GVHD or platelet refractoriness.

Specialized Functions of Class I and Class II MHC Molecules

Despite their similar structures, class I and class II MHC molecules have distinct roles. Key to this distinction is the repertoire of peptides that each MHC molecule binds. Class I MHC binds peptides derived from within a cell and thus displays a cell's intracellular milieu. Class II MHC displays antigens acquired from the extracellular space. Thus, each set of MHC proteins is telling T cells a different tale. In the event of a viral infection, presentation of viral antigens on a cell's class I MHC would indicate to a T cell that the cell is infected. Presentation on class II MHC molecules would instead indicate that virus is present in the environment, but not necessarily within that cell.

The distinct presentation capabilities of class I and class II MHC results from the different mechanisms through which each protein acquires its peptides. Within the cytoplasm of the cell proteins are continuously being degraded by a large proteolytic complex called the *proteasome.*[44] The peptide fragments formed by the proteasome are perfectly sized for binding class I MHC molecules. The production of antigenic peptides may be enhanced and the sites of proteolysis modified by cytokines produced during an immune response, most notably interferon-γ.[45] As class I MHC molecules are synthesized, they are extruded into a membranous compartment within the cell called the *endoplasmic reticulum.* Appropriately sized, proteasomally derived peptide fragments are continuously transported into the endoplasmic reticulum by a special peptide transporter, called *transporter of antigenic peptides,* or TAP1/2.[46,47] The transported peptides can then bind to the nascent class I MHC molecules (Fig. 2–5).[48] MHC molecules bound to peptide are then transported to the cell surface.

Class II MHC molecules take a different route to the cell surface. They are also extruded into the endoplasmic reticulum. However, unlike class I MHC molecules, they bind to a protein called the *invariant chain* as they are synthesized (Fig. 2–6). A peptide segment of the invariant chain folds into the peptide-binding groove of the class II molecule, blocking any other peptides from binding. Rather than going directly to the cell surface like class I MHC molecules, the class II molecules are first diverted to specialized vesicles, or membrane-contained compartments, within the cell where they meet up with extracellularly derived antigens.[49–51]

Cells may take up external antigens through a variety of processes, including phagocytosis, or wholesale consumption of cells or particles; pinocytosis, or internalization of small

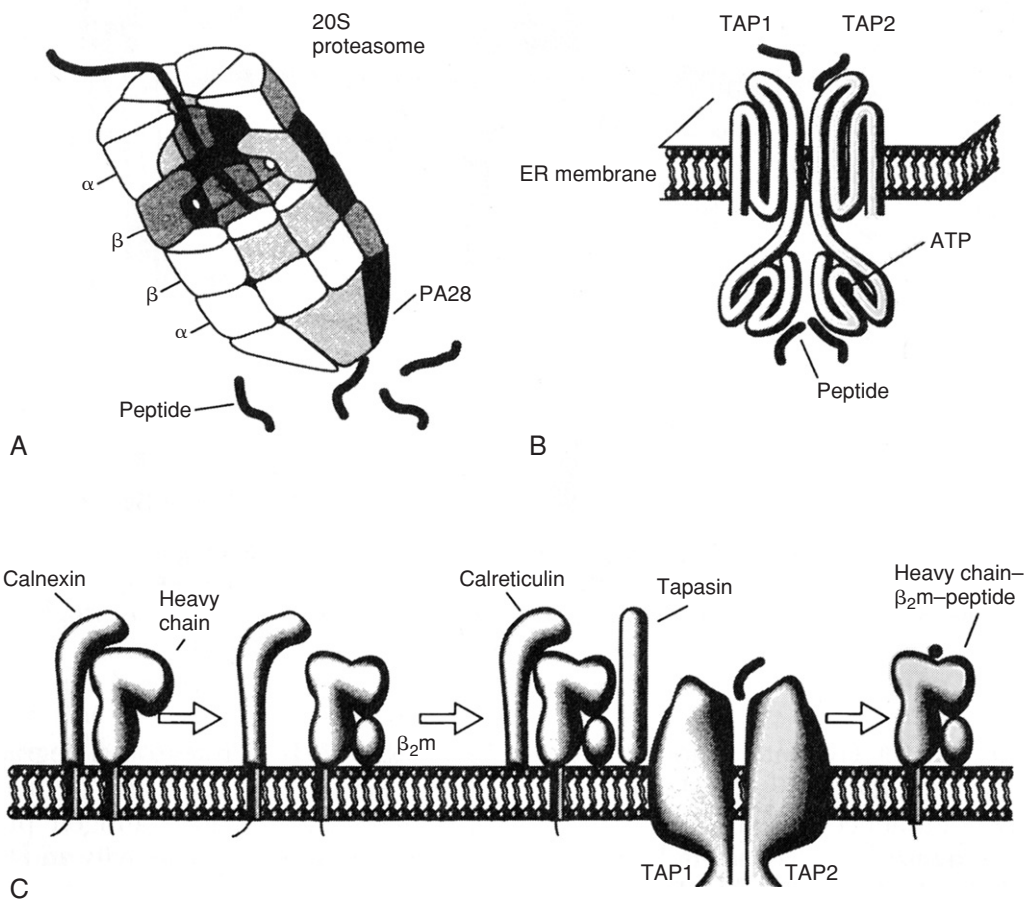

Figure 2–5 **A,** Schematic drawing of a cut-open 20S proteasome generating peptide fragments from an unfolded polypeptide chain threaded into the narrow entry formed by an outer ring of β-type subunits. Cleavage occurs in the central cavity formed by two seven-membered rings of β-type subunits. A PA28 regulator complex, inducible by IFN-γ is bound at the bottom of the cylinder. **B,** Hypothetical cross-section of TAP1/TAP2 heterodimer embedded into the endoplasmic reticulum membrane. The adenosine triphosphate (ATP)-binding domain, which extends into the cytoplasm, is shown. ATP cleavage provides energy for peptide translocation. **C,** Maturation of class I molecules in the endoplasmic reticulum. Nascent class I heavy chains initially associate with calnexin. On binding of β_2-microglobulin, the heterodimer dissociates from calnexin and forms a complex with calreticulin, tapasin, and TAP1/2. After peptide binding, the heavy-chain β_2-microglobulin complexes are released and exit to the cell surface. (From Koopman JO, Hammerling GJ, Momburg F. Generation, intracellular transport, and loading of peptides associated with MHC class I molecules. Curr Opin Immunol 1997;9:81.)

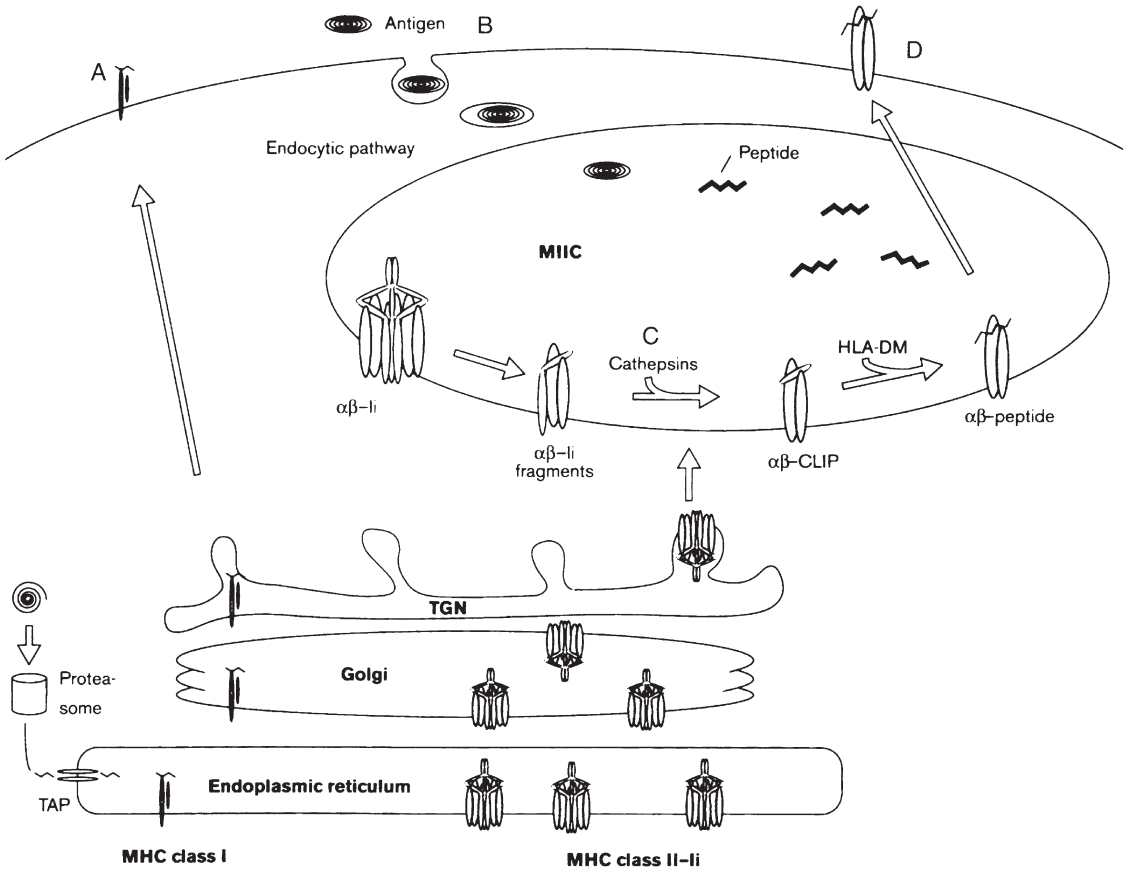

Figure 2–6 Intracellular pathways of class I and class II MHC molecules. Class I MHC molecules acquire antigenic peptides, generated by the proteasome in the cytosol, that are translocated into the endoplasmic reticulum by the TAP molecules (bottom of figure). The class I MHC–peptide complex is transported through the Golgi complex directly to the cell surface for presentation to CD8 T cells (**A**). In contrast, class II MHC molecules acquire antigenic peptides derived from antigens that are internalized in the endocytic pathways (**B**). Class II MHC heterodimers associate in the endoplasmic reticulum (bottom of figure) with invariant chains to form nonameric αβ–Ii complexes. At the trans-Golgi network (TGN), these complexes are targeted to class II MHC compartments (MIIC) in the endocytic pathway as a result of targeting signals within the Ii cytoplasmic tail (not shown). There the class II MHC-associated Ii is degraded in distinct steps, at least partially by cathepsin proteases (**C**), leaving a peptide from Ii in the class II MHC–peptide-binding groove. This peptide is exchanged for antigenic peptides in a process catalyzed by HLA-DM molecules. Peptide-loaded class II MHC complexes are then transported to the plasma membrane for presentation to CD4 T cells (**D**). (From Pieters J. MHC class II restricted antigen presentation. Curr Opin Immunol 1997;9:91.)

amounts of the extracellular fluid; and receptor-mediated internalization, which may occur through bound immunoglobulin or sugar-binding receptors such as the mannose receptor.[52–54] This material is broken down by enzymes within the endocytic, or internalization, pathway. Vesicles containing endocytosed and degraded material merge with the class II MHC containing vesicles. The invariant chain is degraded by proteases at this point, and vesicular peptides can then bind within the class II MHC-binding groove. The class II MHC, with externally derived bound peptide, then makes its way to the cell surface.

T-Cell Co-receptors and the Recognition of Class I and Class II MHC Molecules

MHC molecules present the antigenic universe to T lymphocytes. Considering the different types of antigens presented by class I and class II MHC, intracellular versus extracellular, it is not surprising that these molecules will engage different types of T cells and that this engagement will result in different types of responses. To understand how this occurs requires some background in how T cells recognize antigen.

The variable α and β chains of the TCR recognize peptide–MHC complexes. However, their affinity for peptide–MHC is poor, approximately 100- to 1000-fold lower than the binding affinity, or interaction strength, of antibodies for their target antigens.[55,56] For most TCRs, this interaction is too weak and too transient to generate a signal capable of fully activating a T cell. The TCR is able to signal because it also receives assistance from co-receptors called CD4 and CD8. CD4 binds to class II MHC molecules and CD8 binds to class I MHC molecules. When the TCR engages cognate peptide–MHC, CD4 or CD8 co-associates.

CD4 and CD8 are transmembrane proteins that perform two tasks.[57] First, because they both associate with the TCR and bind MHC at a site different from where the TCR binds peptide–MHC, they increase the binding affinity of the TCR complex for peptide–MHC. Second, and more importantly, they carry bound to their intracellular domain an enzyme of the src family, called lck (Fig. 2–7).[58] Lck is a type of enzyme called a *tyrosine kinase*. It adds phosphates to certain tyrosine residues present in proteins. Tyrosine phosphorylation of the γ, δ, ε, and ζ chains of the TCR is the first step in generating a signal once a TCR recognizes antigen. The complex of CD4 or CD8 co-receptor with the TCR and peptide–MHC aligns the lck kinase with specific conserved tyrosines present within the signaling chains of the TCR called *immunoreceptor tyrosine-based activation motifs,* or ITAMs.[59] Once phosphorylated, these ITAMs

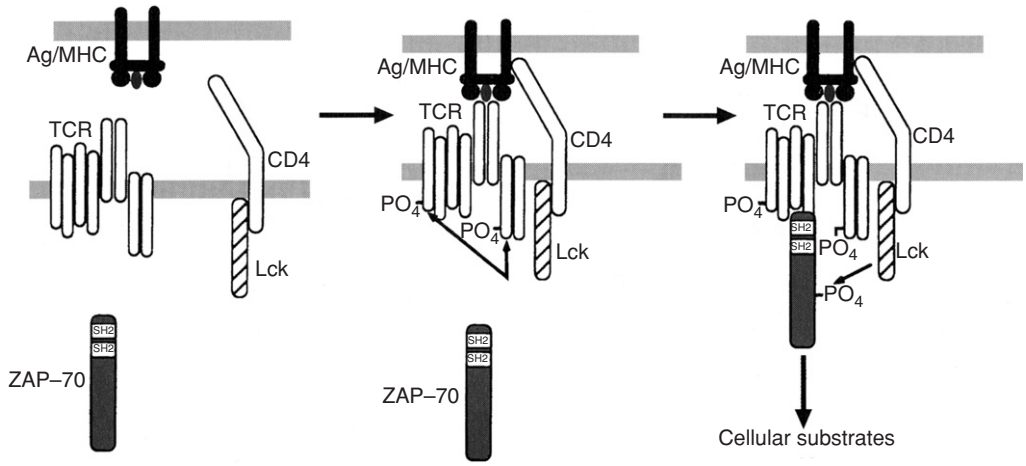

Figure 2–7 Model of TCR, Lck and ζ-associated protein (ZAP)-70 interactions during antigen recognition by a CD4 T cell. The phosphorylation of tyrosine residues of the immunoreceptor tyrosine-based activation motifs within the ζ and CD3 chains has been simplified. (From Weiss A. T-cell antigen receptor signal transduction: A tale of tails and cytoplasmic protein kinases. Cell 1993;73:211.)

serve as docking sites for additional proteins, particularly ZAP-70, another tyrosine kinase that is in turn phosphorylated and activated by lck. This triggers a cascade of signaling inside the cell as additional proteins are recruited to these phosphorylated molecules. In a manner analogous to how the coagulation cascade may be triggered by single event, such as exposure to tissue factor, a low amplitude signal that initially results from TCR–MHC engagement is enzymatically amplified within a T cell. The impact of CD4 and CD8 is dramatic, and it has been estimated that these molecules enhance signaling through the TCR by a factor of 100.[57] Through its sophisticated signaling apparatus, T cells may be discriminately stimulated by 100 or fewer antigen–MHC complexes on the surface of an APC.[60]

Mature T cells express either CD4 or CD8 and do not co-express both of these. This contrasts with their progenitors that develop in the thymus, which co-express CD4 and CD8. During development, these $CD4^+D8^+$ thymocytes are tested.[61] Cells that interact strongly with self-antigen–MHC complexes in the thymus are deleted in a process termed *negative selection.* Negative selection is a major mechanism through which the adaptive immune repertoire is depleted of self-antigen–specific T cells. Cells that do not interact with MHC present in the thymus do not receive necessary survival signals and undergo death through neglect. In contrast, in a process termed *positive selection,* cells with receptors that interact loosely with class I MHC molecules receive survival signals, downmodulate CD4, and are left expressing only CD8. Thymocytes that interact with class II MHC downmodulate CD8 and become CD4-expressing T cells. Thus, T cells can be divided into two major groups based on their interaction with either class I or class II MHC molecules, and these groups can be identified by the alternative expression of CD4 or CD8. Further, CD4 and CD8 define classes of T cells with distinct functional potentials.

Cells That Present Antigen

Because class I MHC presents antigens derived from intracellular pathogens, like viruses, or that result from intrinsic abnormalities, such as malignant transformation, it is important that all cells capable of self-propagation express class I MHC. $CD8^+$ T cells recognizing class I MHC-derived antigens may eliminate these aberrant or infected cells. The majority of nucleated cells indeed express class I MHC constitutively, though class I MHC expression can be enhanced by cytokines, such as in the setting of inflammation.[62]

Not all cells need to express class II MHC, which presents external antigens. Class II MHC expression is limited to specialized cells that provide T cells with environmental information. These include professional APCs, dendritic cells, macrophages, B cells, and endothelial cells, though other cell types may be induced to express class II MHC in the context of inflammation.

Of the professional APCs that present antigen to T cells on class II MHC, dendritic cells are particularly efficient. They reside in tissues in a quiescent state. When activated by any of a large variety of inflammatory stimuli, such as cytokines or Toll-like receptor signals, they sample antigens from their environment, which they present on cell surface class II MHC molecules.[30] After accumulating large quantities of antigen, the dendritic cells cease internalizing antigen and migrate to lymphoid tissues, particularly lymph nodes, where they present antigen to lymphocytes.

There are several types of dendritic cells.[63] Some, the follicular dendritic cells, are particularly adept at presenting whole antigen to B lymphocytes.[64] This is important because B cells recognize whole antigens or large pieces of antigens through their immunoglobulin receptors. In contrast, most dendritic cells, including myeloid, lymphoid, and plasmacytoid dendritic cells, digest antigens into small fragments and present these to T lymphocytes. Because of the scarcity of lymphocytes specific for any single antigen, presentation in specialized lymphoid tissue is essential. The professional APCs structure themselves into a reticular network through which lymphocytes continuously and rapidly percolate.[65] After a dendritic cell is stimulated through its Toll-like receptor or other receptors, it may secrete chemokines that will attract T lymphocytes to it and costimulatory molecules that can activate them. The lymphocytes scan these dendritic cells with their antigen receptor for the presence of cognate antigen. With recognition through their antigen and costimulatory receptors, the lymphocytes pause, alter their metabolism, and modulate gene expression. They may then expand and differentiate into effector forms.

Other professional APCs are macrophages and B lymphocytes. Macrophages are potent phagocytic cells when activated

and may internalize a variety of different pathogens as well as dead and dying cells. Macrophages may present the antigen acquired at the site of tissue injury or within lymphoid organs and are important in guiding some types of T-cell responses. B cells primarily internalize antigens through their BCR, surface immunoglobulin. The high affinity of the BCR for specific antigens allows them to focus small quantities of antigen present in the environment and to display this to cognate antigen-specific T cells.

Functionally and Phenotypically Distinct Classes of T Cells

T cells are categorized into discrete groups based on their phenotype, function, and differentiation potential. The broadest categorization relates to the type of TCR expressed. The large majority of T cells express the αβ TCR described above, though a small number of cells express an alternative receptor composed of a parallel heterodimer of chains called γ and δ. These γ and δ chains recognize antigen–MHC complexes and are distinct from the signaling γ and δ chains that are part of the CD3 complex. Indeed, γδ TCR associate with the CD3 and ζ signaling chains, forming a signaling complex identical to that of αβ receptors. The function of γδ T cells is unclear. Some of these cells reside in lymphoid tissue and have a highly diverse receptor repertoire. Other γδ T cells reside in intraepithelial spaces. These cells have limited receptor diversity within a specific location. This suggests that they recognize relatively invariant molecules, either pathogen or host derived.[66] Indeed, some γδ T cells recognize nonclassical, nonpolymorphic class I MHC molecules called class Ib MHC.[67] Recent data indicates that they may also efficiently present antigen to αβ T cells and may promote the rapid induction of αβ T-cell responses after they are activated.[68] Therefore, these cells may act more as facilitators and regulators rather than mediators of adaptive immunity.

The more common αβ class of T cells is typically divided into helper and effector classes. Helper T cells integrate the environmental cues they receive and then signal to other cells, effector cells, orchestrating their response. Helper T-cell signals may include the release of cytokines, such as IL-2, IL-4, and IFN-γ. They also may signal by interacting with other cells through cell surface receptors. Helper T cells fall largely in the CD4 class of T cells. As a consequence, often the terms helper T cell and CD4 T cell are used interchangeably. On a biological level, this is inaccurate and should be avoided. CD4 T cells in some circumstances have effector functions and CD8 T cells may have helper activities. Nevertheless, it should not be surprising that CD4 T cells tend to be dominantly helper cells by nature. CD4 T cells probe the antigenic environment through class II MHC. Their response to environmental cues that may suggest danger should not be directed against the APC, which is merely a messenger carrying antigen to the T cell. They must choreograph a broader response that will directly target harmful antigens.

When a freshly formed CD4 T cell exits the thymus it is "naive," never having seen its cognate antigen. The cell will home to lymphoid tissues, occasionally circulating through the bloodstream to a different lymphoid location.[69] As it does this, it searches for antigen able to stimulate its TCR, which is delivered to it by APCs present within lymphoid tissue. Once stimulated this T cell may differentiate into one of a variety of forms. Two of the best studied types of CD4 T cells are Th1 and Th2 cells.[70,71] Cytokines secreted by Th1 cells, such as IFN-γ and TNF-β, are responsible for delayed-type hypersensitivity (DTH) reactions.[72,73] Th2 cells, which secrete IL-4, IL-5, IL-10, and IL-13, are responsible for allergic responses.[71,74]

In the DTH response, Th1 T cells stimulate B cells to produce specific antibodies that efficiently activate complement after antigen binding. The Th1 cells also migrate to sites of antigen presentation in tissues. Once there, they secrete cytokines, such as IFN-γ and TNF, and chemokines that promote the recruitment and activation of macrophages, additional lymphocytes, and other inflammatory cells.[75,76] Activation of endothelial cells leads to a loss of vascular integrity and the development of induration, a hallmark of the DTH response. The activated macrophages locally present antigen and amplify the immune response. Macrophages also serve as primary effector cells, ingesting and eliminating pathogens, and producing reactive oxygen species that can kill microorganisms. If this response is unable to clear the inciting agent, granuloma formation and scarring may wall it off.

In Th2 responses, CD4 T cells stimulate the production of antibodies that may be neutralizing or promote antibody-dependent cell-mediated cytotoxicity. Cytokines produced by the Th2 cells activate and promote the expansion of eosinophils and other cell types. Th2 T cells prominently support the production of IgE, which binds specific high-affinity receptors on mast cells and basophils.[77] Antigen crosslinks these antibodies, thereby activating the mast cells and basophils. This induces the release of histamine and other BRMs that are associated with allergic or anaphylactic symptoms, such as vascular dilatation, mucus production, urticaria, and diarrhea. We commonly associate these symptoms with pathologic responses to allergens and not with the clearance of infections. However, Th2 responses appear to be important for the clearance of some parasitic infections.[78,79]

The final form a naïve T cell differentiates into is determined by its microenvironment after antigen stimulation.[80,81] Th1 cell differentiation is promoted by the presence of IL-12 and IFN-γ. Th2 cell differentiation is promoted by the presence of IL-4 and prostaglandin E_2. These stimuli may be produced after innate immune signaling in cells. IL-4 is produced by activated mast cells and basophils.[82–84] Activated dendritic cells may produce IL-12 and the closely related IL-23.[82,85] NK cells may produce IFN-γ.[86] These differentiation cytokines may also be produced by T cells themselves. Th1 cells produce IFN-γ, which further promotes Th1 differentiation and inhibits Th2 differentiation. Th2 cells produce IL-4, which promotes Th2 and inhibits Th1 development. Thus Th1 or Th2 antigen-specific T cells that developed in prior immune responses or in an earlier phase of an active immune response may polarize a nascent immune response, promoting the development and expansion of T cells of their own class while inhibiting those of other classes. This ensures an unadulterated response to a particular pathogen type, DTH or allergic in the case of Th1 and Th2 cells, respectively.

CD8 T cells are typically effector in nature. When activated they differentiate into a class of cells called *cytotoxic T lymphocytes* (CTLs). In many circumstances this differentiation depends on signals provided by CD4 helper T cells.[87,88] One manner by which stimulated CD4 T cells do this is through the upregulation of a TNF-family protein, CD40L, on their cell surface.[89] CD40L interacts with CD40 on the surface of APCs, signaling into the APC. This signal is important to "license" the APC, that is, induce in the APC production of cytokines and signaling molecules that are needed to adequately stimulate the CD8 T cell. If a CD8 T cell does not receive these supplemental signals, it will not appropriately

expand and differentiate in response to antigen and may die after antigen encounter.

When a CTL's TCR encounters and engages its target MHC–antigen complex on a cell, it extrudes preformed granules that contain lytic proteins.[90] These proteins include perforin, which forms pores in the membranes of the target cells, and granzymes, enzymes that kill targets through a preprogrammed cell death pathway called *apoptosis*. They also include a protein called fasL, which binds to a receptor called fas on many cell types, also inducing apoptosis. The absence of adequate lytic activity can have severe consequences. Patients with mutations in perforin develop a disease called *hemophagocytic lymphohistiocytosis*.[91,92] Failure to control infections results in an unrestrained activation of the immune system that is most often fatal.

Regulation of T-Cell Responses

The effector responses that T cells coordinate can cause substantial bystander damage to host tissues if unrestricted. Because of this, homeostatic mechanisms that limit immune responses are essential. There are several such mechanisms.

One mechanism is the apoptosis, or programmed cell death, of lymphocytes. After immune activation, T cells proliferate profusely. This is physically manifested by the splenomegaly and adenopathy commonly identified with infection. Failure to eliminate this expanded cell population would result in a plethora of activated immune effector cells. Most of these cells, however, die through apoptosis.[93–95] Members of the TNF family of proteins are particularly important for this. For example, in many circumstances activated T cells will express a pair of TNF family molecules, fas and fasL. When fasL engages fas, it stimulates the fas receptor. This activates a set of cellular proteases called *caspases* that can cause a loss of mitochondrial and ultimately cellular integrity. In the absence of molecules that inhibit apoptosis, caspase activation ultimately leads to cell death. Dysfunctional apoptosis mechanisms in lymphocytes can lead to autoimmunity by allowing the persistence of self-reactive T cells that normally would be eliminated. Indeed, patients with mutations in fas or apoptotic signaling develop a disease called *autoimmune lymphoproliferative syndrome*.[96]

Cytokines and other BRMs may also restrict immune responses. Many cytokines have dual properties, both enhancing and suppressing immune effector mechanisms even within a single type of immune response. For example, IFN-γ activates macrophages and other effector cells and promotes Th1-cell differentiation. It also inhibits proliferation and may in some circumstances promote apoptosis.[86] A good example of the dual effects of IFN-γ is observed in an experimental murine model of multiple sclerosis, an autoimmune disease that is predominantly Th1 in nature. IFN-γ produced early in the pathologic response promotes the induction of Th1-polarized T cells and therefore disease development. Later in the disease course, IFN-γ is protective, and its neutralization exacerbates disease.[97,98]

Although many cytokines have mixed pro- and anti-inflammatory effects, some cytokines have dominantly inhibitory roles.[99–101] For example, transforming growth factor-β (TGF-β) strongly suppresses T-cell activity. Mice genetically modified so that their T cells are unable to respond to this cytokine develop a spontaneous lethal autoinflammatory condition. IL-10, while able to activate B cells, is also a critical downregulatory cytokine for activated macrophages. Mice lacking IL-10 develop spontaneous inflammatory bowel disease.[102]

Negative signaling is not limited to cytokines but can also occur through cell associated proteins. As mentioned above, professional APCs provide T cells with access to costimulatory proteins. These generally promote signaling in the context of TCR activation.[29] The proteins B7.1 and B7.2 are prime examples.[103] These are upregulated on APC after exposure to Tlr signaling or CD40L, and bind to CD28 on T cells. In the absence of adequate costimulatory signaling a T cell will become unresponsive to its cognate antigen, a condition called anergy, or may die.[31] The B7 proteins are only one of a large group of essential costimulatory molecules expressed on APC.

However, costimulatory molecules need not transduce a positive signal into a T cell. Examples include PD-1L and B7h3, which when expressed on an APC downmodulate T-cell signaling and T-cell responses.[104,105] T cells may also express variant ligands for a single costimulatory molecule. Thus CD28 transduces a strong growth and survival signal when it engages B7 ligand. But a similar molecule, CTLA-4, when expressed on T cells, binds the same B7 ligands but downmodulates T-cell activation.[106,107] Mice that lack CTLA-4 develop uncontrolled lymphoproliferation. Temporal regulation of CD28 and CTLA-4 on a T cell may specify the magnitude of the T-cell response. Whereas most T cells express CD28 constitutively, they only express CTLA-4 after activation. Thus initial antigen exposure provides a strong signal to T cells. This signal is downmodulated by CTLA-4 if the exposure persists.

Not all T cells are involved in choreographing and mediating immune effector functions. The dominant role of several classes of T cells is the suppression of immune responses. These antagonize the pro-inflammatory activities of effector T cells. One important category of regulatory T cells co-expresses CD4 and the high-affinity receptor for IL-2, CD25.[108,109] Development of these cells is defined by the expression of a DNA-binding protein, or transcription factor, called FoxP3. Patients with the IPEX syndrome (immune polyendocrinopathy, X-linked) have mutations in this transcription factor and lack these regulatory T cells.[110] Overwhelming multiorgan autoimmunity develops early in life. When stimulated by antigen, FoxP3-expressing regulatory T cells inhibit T-cell responses both through direct cell–cell contact effects and through the production of cytokines, particularly IL-10 and TGF-β. Other classes of regulatory cells, which have been given different names by investigators, including Th3 and Tr1 cells, primarily inhibit immune responses through the production of regulatory cytokines.[99,101,111] Again, TGF-β and IL-10 seem to be critical.

The complexity to immune regulation parallels the complexity of immune activation. At any point in time the integration of many different signals, some promoting activation and others signaling restraint, will define the ultimate direction taken.

B-Lymphocyte Responses

B lymphocytes are critical effector cells for immune protection. They act through the production of immunoglobulin, or antibodies. Antibodies specifically bind to target antigens. By so doing, they may sterically block the function of some antigens, such as toxins, enzymes, and receptors. Antibody binding may promote complement fixation and thereby the lysis or phagocytosis of cells. Antibody–antigen complexes may crosslink

immunoglobulin receptors, Fc receptors, on the surface of effector cell types, such as NK cells, neutrophils, macrophages, and mast cells.[112,113] If the Fc receptor is an activating form of the receptor, it will stimulate functions capable of clearing or neutralizing the antigen through a variety of mechanisms, including phagocytosis, antibody-dependent cell-mediated cytotoxicity (ADCC), cytotoxic granule release, and the generation of reactive oxygen and other cytocidal compounds. The antibody, or humoral, immune response is therefore essential to host defense. In its absence, there is a dramatic increase in the susceptibility to and severity of infections.[114]

Like the T-cell repertoire, the B-cell repertoire is richly diverse, with billions of possible unique receptors. Like T cells, B cells only express a single receptor on their surface. And like T cells, B cells are not constitutively activated, secreting random immunoglobulins. Rather, they produce soluble immunoglobulins only after being activated through their antigen receptor. Unlike T cells, B cells do not recognize antigen complexed with MHC; they recognize whole antigens.

B cells can differentiate to secrete antibodies in the absence of T cells. These responses are called *T-independent* or *helper-independent responses.*[115,116] There are two types of T-independent humoral immune responses. In T-independent-1 responses, the antigen is able to simultaneously stimulate the B lymphocyte through the BCR and other activating receptors. For example, B cells specific for LPS will receive stimulatory signals both through their antigen receptor and through their LPS-specific Toll-like receptor. This may occur in the setting of a gram-negative bacterial infection. Whereas high concentrations of LPS will polyclonally stimulate all B cells through Tlr4, low doses will only simulate those T-independent-1 B cells that are able to concentrate the LPS with their BCR. The combined Toll-like receptor/BCR signal promotes antibody secretion. In T-independent-2 responses, the antigen is not intrinsically stimulatory, but acts by cross-linking a threshold number of BCRs on the B lymphocyte. Too strong a BCR stimulus can turn off a B lymphocyte, and too small a stimulus will not adequately activate a B cell. However, intermediate levels of stimulus may be sufficient to activate subgroups of B lymphocytes, most prominently B cells that express the CD5 antigen (B-1 B cells) and marginal zone B cells.

Often the immune response to T-independent antigens is directed against polysaccharides and other polyvalent structures present in the cell walls of pathogens. The T-independent response may allow an early antibody response against these antigens. This antibody may promote internalization of infecting organisms by phagocytes and antigen presentation to T lymphocytes. Activation of the T-cell response may then further drive the B-cell response through the provision of T-cell help in the form of cytokines and other signaling molecules. Patients with Wiskott-Aldrich syndrome fail to produce T-independent responses to bactetrial antigens and consequentially are at great risk for infection with encapsulated bacteria.[117] T-independent immunoglobulin responses are primarily of the IgM class of antibodies (described in the following section). Further differentiation of the B cell is required to produce other types of antibody, and T-cell help must be provided for this.

Generally, T-cell help is available to promote B-cell responses. As B cells enter the spleen or lymph node from the circulation, they initially enter T-cell rich areas. If the B cell has encountered its antigen, either in the circulation or in the lymphatic tissue, it will internalize the BCR–antigen complex. This will be degraded and presented by the B cell on the surface of its class II MHC molecules. Because B cells internalize antigens almost exclusively through their BCR, they are able to selectively capture and concentrate their specific antigens from the extracellular environment. If a T cell that has been stimulated by its cognate antigen on a dendritic cell or other APC then discovers the same antigen on a B cell, the cells will transiently join together and stimulate each other.[118] The B lymphocyte along with the T lymphocyte will proliferate, expanding typically at the interface between the T and B regions of the lymph node.

The epitope recognized by a B lymphocyte's antigen receptor need not be the same as that recognized by the TCR of the T cell that stimulates it. When the BCR binds to and endocytoses antigen, it may internalize whole proteins; complexes containing multiple proteins, DNA, lipids, and polysaccharides; or even whole organisms. All of this will be digested and presented to T cells on the B cell's class II MHC. The antigenic epitope recognized by the T cell therefore does not need to be identical to that recognized by the B cell, but it must be co-internalized and therefore linked to it. The help provided to B cells by T cells is thus often termed *linked recognition.*[119]

Stimulated B cells that secrete antibodies are called *plasma cells.* These cells functionally transform themselves, upregulating protein synthetic machinery so as to be able to produce large quantities of antibodies. They localize to the medulla, or central core of the lymph nodes, or specific regions of the spleen or bone marrow, where they secrete copious amounts of specific antibodies.[120,121]

Some stimulated B cells will migrate into the B-cell rich follicles of the lymph node or spleen and form what is called a *germinal center.*[122] Germinal centers consist of large numbers of proliferating and differentiating antigen-specific B cells accompanied by smaller numbers of supporting T lymphocytes. Within the germinal centers the B cells are continuously stimulated by antigen presented by follicular dendritic cells. They receive further help from T cells, which promotes their survival, growth, and differentiation. Under the influence of these signals, the B cells may isotype switch, or replace the constant region of their immunoglobulin receptor to allow production of antibody isotypes other than IgM. Isotype switching involves the excision of DNA sequence encoding upstream antibody constant domains, placing the rearranged VDJ region in proximity with a different C region. It is fostered by the expression of CD40L on activated T cells, which binds CD40 on B cells. Cytokines, such as IL-4 and IL-6, also promote B-cell differentiation and isotype switching. B cells from patients lacking CD40L or an enzyme required for DNA rearrangement, activation-induced cytidine deaminase, fail to isotype switch and exclusively produce IgM.[123,124]

B lymphocytes are capable of an additional trick unavailable to T cells. B cells in the germinal center can actually mutate their BCR, a process termed *somatic hypermutation.*[125,126] The mutations are focused in the antigen-binding region of the receptor. Within the germinal center a process of selection occurs for B cells based on their affinity for antigen. As antigen recedes, the rare B cells in which immunoglobulin mutations have increased their affinity for antigen will survive best, whereas B cells that less effectively bind, internalize, and concentrate antigen will fail to receive necessary survival signals and will perish. Due to somatic hypermutation, B cells may acquire mutated antibodies that have 100-fold or

higher affinity for antigen than their antecedent antibodies. Affinity-matured B cells may then form plasma cells, secreting high-affinity antibody. Alternatively, high-affinity B cells may become quiescent, forming what is called a *memory B cell*. Memory cells are long-lived formerly activated lymphocytes, either T or B, capable of rapid response on restimulation.[127] Because of the presence of memory cells, the antibody response on secondary stimulation is of a higher magnitude and affinity than the primary response that develops after initial exposure to antigen.

Antibodies

Antibodies come in several forms, each of which has the same basic structure, consisting of two linked dimers of a heavy and light chain. Each of the chains includes tandem globular domains called *immunoglobulin domains* that are conserved within the immunoglobulin superfamily of proteins (Fig. 2–8).[128] The heavy chain is composed of a variable region encompassing the V, D, and J segments, and a C region with three or four immunoglobulin domains depending on the antibody isotype. This heavy chain is linked through a disulfide bond (two cysteines bound together through their sulfur moiety) to a light chain. The light chain consists of V and J segments linked to a constant region with a single immunoglobulin domain. Two identical heavy-light chain dimers are fastened by disulfide linkages between the two heavy chain genes adjacent to the second immunoglobulin domain. Each heavy and light chain pair may independently bind antigen, and a single immunoglobulin monomer thus has a valency for antigen of 2.

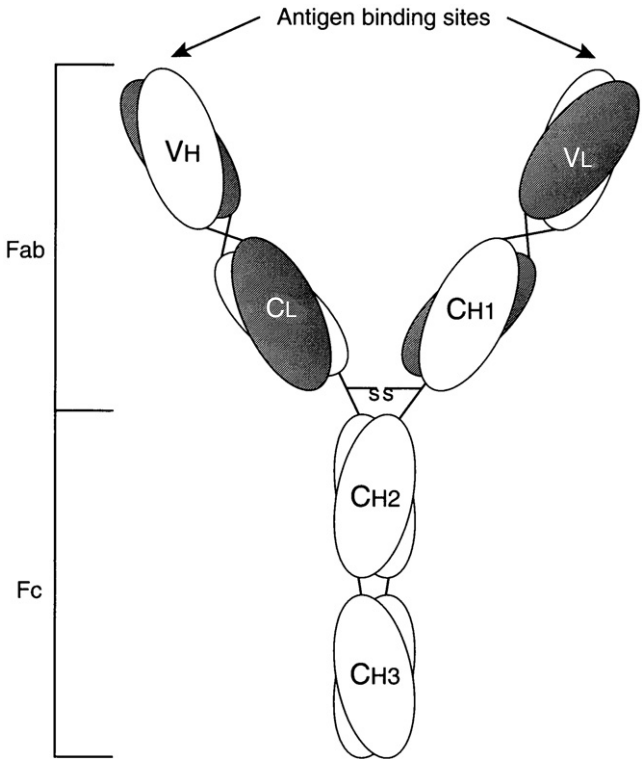

Figure 2–8 Structure of a prototypical, monomeric, secreted antibody molecule. Ovals represent immunoglobulin domains. Heavy chains are indicated by white fill, light chains by gray fill. Polypeptide linkages are indicated by lines. A single representative disulfide linkage between the hinge regions of the heavy chain is indicated; other interchain and intrachain disulfide bonds are not shown.

Different functional regions are encoded within immunoglobulin molecules. The Fv consists of the paired heavy and light chain variable domains. Fv are not independently stable when separated from the rest of the immunoglobin molecule; however, engineered single chain Fv in which the heavy and light variable domains are genetically linked have been created and are capable of binding antigen. These engineered scFv may become increasingly common as the use of engineered antibodies for therapy and diagnostics becomes more routine.[129–131]

The addition of the first constant region domain to the Fv domain incorporates a disulfide linkage between the heavy and light chains and stabilizes the Fv. These Fab (fraction antibody binding) retain the antigen-binding properties of the parent immunoglobulin. Fab fragments may be released from immunoglobulin molecules by protease digestion.

The final two or three constant regions of the heavy chain form the Fc domain. Where the Fab domains connect to the Fc stalk, there is a flexible hinge that allows each Fab domain to independently bend. This helps the antibody bind to multivalent antigens, where the spacing between individual epitopes may vary. The Fc binds to immunoglobulin-binding receptors on cells, Fc receptors, and is therefore responsible for ADCC and other cell-mediated activities. The Fc also binds complement and participates in the activation of this effector pathway. Fab and Fv antibody fragments lack the Fc domain and therefore lack these activities.

Immunoglobulin heavy chains come in five basic varieties—μ, γ, δ, ε, and α. When linked to either of the two varieties of light chain—κ or λ—these form IgM, IgG, IgD, IgE, and IgA, respectively, the different isotypes of immunoglobulin. Each of the immunoglobulin isotypes come in a membrane-bound form expressed on the surface of B cells. A transmembrane domain pierces the cell membrane, attaching the immunoglobulin to the cell surface. Transmembrane forms of immunoglobulin associate with cell membrane proteins, called Igα and Igβ, which allow BCR signaling in a manner analogous to the CD3 chains of the TCR. All isotypes except IgD may also be secreted, in which case the antibody protein is synthesized without the transmembrane anchor. The role of IgD is poorly characterized. Cells expressing IgD also express an IgM version of the same antibody.

The secreted forms of different antibodies differ structurally. Secreted IgM consists of five immunoglobulin molecules that are linked together by a junctional chain, forming a pentamer with 10 antigen-binding sites. IgA may be secreted as a single immunoglobulin, and this is its most common form in plasma. However, IgA produced by plasma cells underlying epithelia in the gut, respiratory, or reproductive tracts typically is dimeric, and therefore antibodies secreted into these locations have four antigen-binding sites.[132] The remaining immunoglobulin isotypes are only produced as monomers with two antigen-binding sites.

Soluble antibody can bind cognate antigen in solution. The binding affinity an antibody has for its antigen is related to the chemical energy of binding of the Fv domain with its antigen. When an antigen is polyvalent, however, the ability of immunoglobulin to multimerize with its respective antigen will significantly increase its ability to bind the antigen. In this circumstance dissociation of the antibody from antigen would not simply require the dissociation of a single interaction, but would require all Fv regions to simultaneously disconnect from the antigenic particle. This increases net binding capacity, or avidity, of immunoglobulin molecules.

Table 2–3 **Properties of Immunoglobulin Classes**[138]

Ig Class	Conc (mg/dL)	No. of Ab	% Intravascular	Half-life (d)	Complement Fixation (– to ++++)	Agglutination Capacity	Placental Transport	Epithelial Transport
IgM	120–400	5	41	5–6	++++	++++	–	+
IgG	800–1600	1	48	18–23		+/–	+	–
IgG1		1			+++			
IgG2		1			+/–			
IgG3		1			+++			
IgG4		1			–			
IgA	40–220	1–2	76	5–6.5	+/–	++	–	++++
IgE	17–450 ng/mL	1	51	2.3	–	–	–	–

Increased avidity is particularly important for IgM. IgM is formed early in the course of an immune response, and because it will not have undergone somatic hypermutation, is typically of low affinity. This is compensated for by its high valency and thereby enhanced avidity.

As described, naive B cells secrete IgM when stimulated to produce antibody. A minimal requirement for B cells to switch isotypes is the engagement of cell surface CD40 by CD40L on T cells. The isotype the B cell converts to depends on the inflammatory environment at the time of isotype switching. Cytokines are particularly important. IFN-γ will promote formation of subclasses of IgG that efficiently bind complement. IL-4 will promote IgE formation. TGF-β promotes the formation of IgA.[133–135] These different antibody isotypes and even subclasses within isotypes have distinct functional properties, including complement fixation, Fc-receptor binding, and transport across epithelial barriers or the placenta. Some of these properties are listed in Table 2–3.

All antibodies are not equivalent, and the properties an antibody possesses will define its functional capabilities. These properties include the antibody isotype and valency, affinity for antigen, temperature dependence in binding, and titer. For instance, IgM cold agglutinins generally bind poorly at physiologic temperatures and require high titers for clinically significant effects. Some antibody isotypes are most efficient at fixing complement, and anti-RBC alloantibodies of these isotypes are of most concern for intravascular hemolytic reactions. Only IgG isotype anti-RBC antibodies pass the placenta and cause hemolytic disease of the newborn. IgE antibodies bind to specific IgE receptors on mast cells and when crosslinked activate the mast cells to secrete histamine and other BRMs that generate allergic symptoms. Sometimes we can take advantage of the properties of an antibody. For example, the rate of IgM diffusion into the extravascular space is low compared with IgG. This facilitates IgM removal by plasmapheresis.

CONCLUSION

The immune system is a dynamic web of interacting cells and molecules that protect our bodies from harm. In the practice of transfusion medicine, we may only become aware of the immune system when our patients manifest symptoms, such as when they become alloimmunized or develop allergic reactions. However, underlying these responses are not only end-effector molecules, cytokines, or antibodies, but also complex pathways of innate and adaptive immunity involving many cell types and continuous intercellular dialogue. This dialogue occurs even when we fail to clinically observe an immunologic consequence of transfusion. It even occurs within stored blood components, which respond to their storage conditions by producing cytokines and other BRMs that are then infused into patients.[136,137] The complexity of the immune response leads to unpredictability in the effects of a transfusion. We still cannot predict who will or will not have an adverse outcome to a specific transfusion event. Nevertheless, a continuous conscientiousness toward the nature of the immune response, how the immune response may perturb the intended outcomes of our transfusions, and how transfusion may perturb the immune system itself, can only help inform the clinical decisions we make.

Chapter 3

Principles of the Complement System Central to Transfusion Medicine

Dana V. Devine

The existence of the complement system has great impact on the practice of transfusion medicine. In its normal immune activities, complement functions to kill pathogens, mediate inflammation, maintain the solubility of immune complexes, promote a normal adaptive immune response, and opsonize particles for phagocytosis. However, complement can also mediate pathogenic processes, including anaphylaxis, intravascular hemolysis of transfused blood cells, leukocyte mobilization in transfusion-related acute lung injury (TRALI), and activation of platelets.

The group of proteins known to constitute the complement system was first recognized in the 1880s as the labile bactericidal activity in serum.[1] Paul Ehrlich coined the term for the phenomenon by proposing a model of antibody-mediated cytotoxicity in which a serum factor *complements* the bactericidal activity of antibody. A detailed understanding of the biochemistry of the complement system required the development of techniques that would permit the isolation of individual complement proteins; this technology finally appeared in the 1960s. With the explosion of research activity in the complement field in the 1970s came the recognition that this system was much more complex than had been imagined. This complexity is amply demonstrated by the fact that at least 25 complement proteins are involved in the activation and regulation of that activity known to Ehrlich simply as *complement.*

The understanding of the complement system is made easier by setting a proper context. Like coagulation, the complement system is an activated enzyme cascade. In such cascades, proteins normally circulate in an inactive form, the zymogen. When the pathway is initiated, the first protein in the sequence is converted from a zymogen to an activated enzyme, which acts on the next protein zymogen in the cascade. Such pathways are amplifying, because each enzyme molecule generated can act on multiple substrate molecules. Activated enzyme pathways are also characterized by the presence of regulatory proteins, both humoral and cellular, that prevent the activated enzymes from converting all available substrate.

The nuances of the complement system have long struck fear into the hearts of basic scientist and clinician alike. Clinical aspects of complement biology in the pathophysiology of disease have been reviewed by Morgan[2] and more recently by others.[3,4] This chapter describes the central role of complement in many physiologic processes, including those associated with the use of blood components.

BASIC BIOCHEMISTRY OF THE COMPLEMENT SYSTEM

Classical Pathway Activation

Activation of the complement system occurs via two pathways; with the activation of C3 (the third component of complement), these pathways join to form a common pathway that completes the cascade (Fig. 3–1). The primary function of both pathways is the generation of enzyme complexes that activate C3 by cleaving it to C3b. The antibody-mediated activation of complement occurs by the *classical pathway,* so called because it was the first pathway recognized. Activators of the classical pathway include not only antibody molecules, but also several nonimmunoglobulin proteins (Table 3–1). Only immunoglobulins (Ig) of the M and G isotypes activate complement by the classical pathway. In humans, IgG3 and IgG1 are strong complement activators, but IgG2 is a poor activator, and IgG4 does not activate complement. These differences result fro m variation in the ability of the different IgG subclasses to bind the first component of complement, C1. The ability of an antibody to activate complement, with the accompanying opsonization and perhaps lysis of the cell, parallels the opsonic potential of the IgGs themselves. The varying risk of phagocytic destruction by crystallizable fragment (Fc) receptor-mediated recognition of IgG is an important feature in distinguishing clinically significant antibodies from those with less destructive potential.

C1 is a multisubunit complex that contains the initial antibody-binding subunits, C1q, as well as two types of zymogen subunits, C1r and C1s, that acquire serine protease activity on activation of the complex. Each molecule of C1 contains six C1q subunits, and two each of the C1r and C1s subunits. The fixation of a C1 molecule to the surface of the cell by the C1q subunits requires a minimum of one molecule of IgM or at least two molecules of IgG for efficient activation. C1q itself contains six identical subunits composed of a triple helical region with homology to collagen and a globular domain at the distal end. The proximal end of C1q is associated with the other subunits of the C1 complex, C1r and C1s, in a calcium-dependent manner. Two of the six C1q subunits must be bound by antibody to effect activation. Although a single molecule of IgM is capable of activating complement, it must be bound to antigen, where it assumes a staple-shaped conformation. Fluid-phase or planar IgM does not activate complement, inasmuch as the C1q-binding sites are exposed only in the staple form.[5]

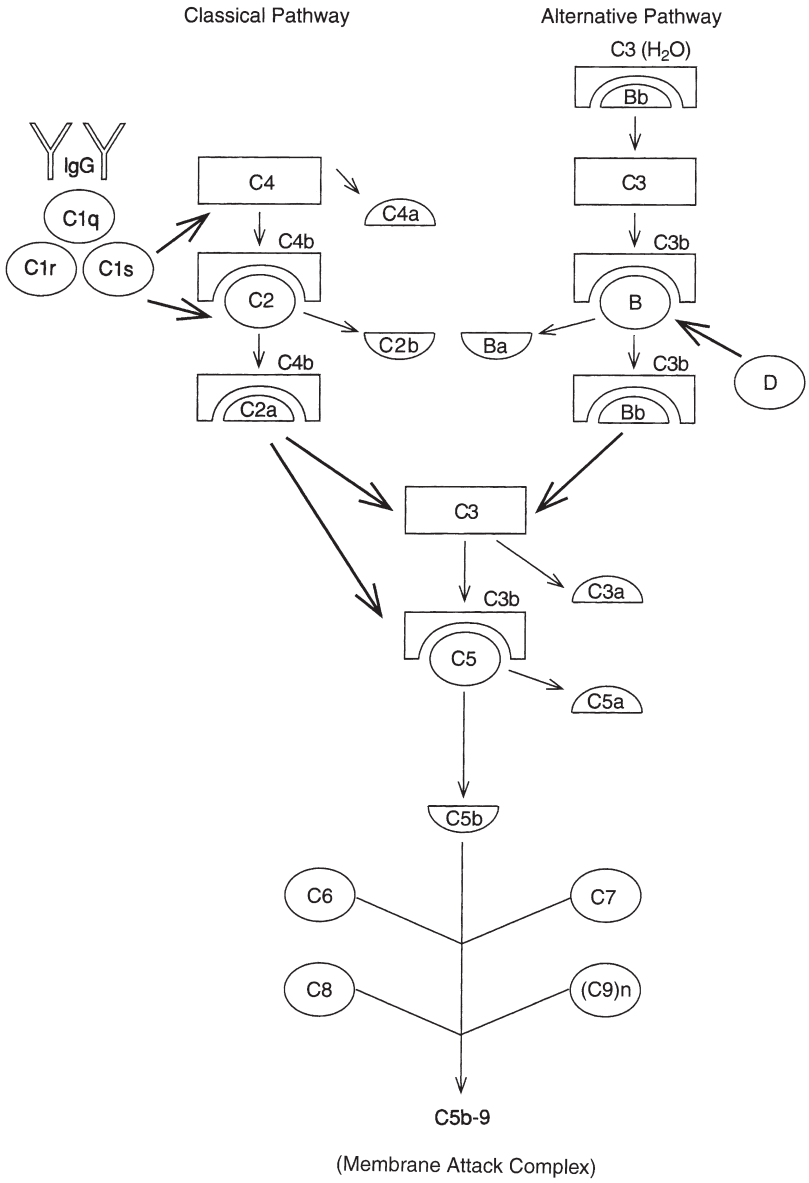

Figure 3–1 The activation pathway of complement. The activation of complement may proceed by the classical pathway or the alternative pathway. Inactive (zymogen) forms of complement proteins are cleaved by activated proteins that have serine protease activity (*heavy arrows*). Once cleaved, a substrate acquires enzymatic activity and acts on the next substrate in the pathway. The membrane attack complex forms by the assembly of the individual components in an enzyme-independent manner. (From Anderson KC, Ness PM. Scientific Basis of Transfusion Medicine, 2nd ed. Philadelphia, Saunders, 2000.)

Once two subunits of C1q are bound to antibody, the molecular conformation changes, in that the angle between the subunits is greatly reduced; the resulting stress on the molecule facilitates the autocatalysis of the C1r subunits.[6] On autoactivation, C1r acquires serine protease activity, which is directed against the C1s subunits. Once C1s is cleaved by activated C1r, it also acquires serine protease activity. This activated C1 complex is the initiation complex of the classical pathway.

Although the majority of classical pathway activation is antibody mediated, antibody-independent activation of the classical pathway has been described in several situations (see Table 3–1). Such activation may involve the direct binding of C1q to a surface, or it may be mediated by other plasma

Table 3–1 **Complement Activators**

proteins, such as C-reactive protein (CRP) or mannose-binding lectin. Activated C1s has the next two proteins in the pathway, C4 and C2, as its substrates. The C4 molecule is cleaved by C1s to C4a and C4b. Some of the C4b molecules bind covalently to the cell surface through a reactive thiol ester bond that is exposed when the C4a fragment is removed; most C4b molecules are inactivated by hydrolysis and never bind to a cell surface. In a magnesium-dependent reaction, a C2 molecule binds to a molecule of C4b; the C2 is then also cleaved by C1s. This cleavage results in the generation of the active serine protease, C2a, which remains associated with C4b. Clearly, the cleavage of both C4 and C2 by the same molecule of C1s is sensitive to the local geometry; deposition of the C4b molecule far from the activated C1 molecule results in the termination of the activation pathway.

The bimolecular complex, C4b2a, is the C3-converting complex of the classical pathway. The cleavage of C3 by C4b2a results in the formation of two fragments, C3a and C3b. C3b, like C4b, contains a reactive thiol ester bond that enables it to bind covalently to the cell surface. The intramolecular thiol ester present within C3 is formed by a transacylation reaction between the thiol group of ^{988}Cys and the gamma amide group of ^{991}Gln.[7] The exposure of this reactive center results in the interaction with cell surface moieties through the formation of an ester or an amide bond.

As indicated earlier, the activation of the classical pathway does not require immunoglobulin. The most recent developments in complement biochemistry have included an appreciation for the role of molecules of the pentraxin and lectin families in the activation of complement. Pentraxins, a family of molecules named for their cyclic pentameric subunit structure, include two proteins that have been implicated in complement activation: CRP and serum amyloid P.[8–10] Both proteins bind C1q, thereby initiating the classical pathway without a requirement for antibody.

Lectin Pathway Activation

The carbohydrate-binding properties of plant-derived lectins are well known in the field of blood banking, in which they are useful phenotyping reagents. Lectins or lectin-like proteins are also found in mammals. One of the C-type animal lectins, mannose-binding lectin (MBL), belongs to a group of soluble pattern recognition receptors. These molecules and their membrane-bound cousins the Toll-like receptors, recognize pathogen-associated molecular patterns located on infectious organisms. MBL recognizes mannose-containing carbohydrates and also binds *N*-acetylglucosamine. MBL binding to its substrates has been reported to mediate complement activation.[11] The hexameric form of MBL is structurally similar to C1q and will bind the $C1r_2s_2$ complex. MBL is found in association with one of three forms of a serine protease, MBL-associated protease (MASP1, MASP2, or MASP3). Complement activation may be mediated by either $C1r_2s_2$ or by the direct action of MASPs. The relative biological significance of the pentraxin and lectin pathways is not fully understood.[12] However, both CRP and MBL are acute-phase reactants and may reach significant serum concentration during infection or inflammation.

Alternative Pathway Activation

A different C3-converting complex is generated by the activation of the alternative pathway of complement. The term *alternative* arises from the fact that this mechanism of C3 cleavage was discovered many decades after the classical pathway. It should in no way be considered a secondary pathway of complement activation, because it is the only pathway of complement that can respond to microorganisms in the absence of specific antibody. It is, therefore, a front-line host defense. Activators of the alternative pathway include a broad spectrum of substances, from renal dialysis membranes to immune complexes to microorganisms (Table 3–2). The initial step in the activation of the alternative pathway is the generation of a partially activated molecule of C3, which has been described as C3b-like.[13] This molecule is presumably generated by the low-grade, spontaneous hydrolysis of C3 that occurs in the body and is not the result of the presence of the activator substance per se. $C3(H_2O)$ has the important characteristic of being able to interact in the fluid phase with the complement protein factor B in a magnesium-dependent manner. Once factor B has associated with $C3(H_2O)$, it is cleaved by factor D, a circulating serine protease that has specificity for factor B bound to $C3(H_2O)$. This cleavage results in the formation of two fragments, Ba and Bb. The Bb fragment has serine protease activity and remains associated with $C3(H_2O)$. The bimolecular complex $C3(H_2O)Bb$ has C3 as its substrate. The $C3(H_2O)Bb$ complex cleaves C3 in the same way as C4b2a, and the resulting C3b molecules can bind covalently to the cell surface. If C3b binds to an activator surface, factor B associates with it and is cleaved by factor D. This results in the formation of an alternative pathway C3-converting complex on the surface of the activator. Because this complex has C3 as its substrate, it produces a feedback amplification loop for the deposition of C3b onto the activator.

The binding of a C3b molecule in the immediate vicinity of a C4b2a or C3bBb enzyme complex produces a trimolecular complex that is capable of cleaving C5. The C3b molecule has a binding site for C5; if the geometry is appropriate, C5 is presented to the enzyme complex, where it is cleaved by C2a or Bb serine proteases. The cleavage produces the fragments C5a and C5b. Although there is a great deal of homology among C3, C4, and C5, there is no reactive thiol ester in the C5 molecule. Therefore, the cleavage of C5 does not generate a fragment capable of binding covalently to a cell surface. The C5b molecule remains briefly associated with C3b before its association with the terminal proteins of the complement pathway.

Formation of the Membrane Attack Complex

Membrane attack complex of complement refers to the association of the complement proteins C5, C6, C7, C8, and C9 to form a potentially cytolytic complex. When C5 is activated in either the classical or alternative pathway, the resulting C5b molecule contains binding sites for the next components in the pathway. This part of the complement pathway is still a cascade, but the activation of a component results in the exposure of binding sites for other terminal complement proteins rather than in the acquisition of enzymatic activity. C5b, but not C5, contains a binding site for C6, which becomes bound while the C5b molecule is associated with its C3b tether. The C5b6 complex may be released from C3b, or it may remain anchored until it binds a molecule of C7. Once C7 is attached, the trimolecular complex undergoes a transition in which the normal hydrophilic character of the

Table 3–2 **Characteristics of the Proteins of Complement**

individual members of the complex is lost and a transient hydrophobic character is acquired. At this time, C5b-7 may associate with a membrane through the hydrophobic region; if it fails to interact with a membrane, the complex inactivates by self-aggregation or by interaction with the inhibitors described later.

Once C5b-7 is membrane associated, a binding site for C8 is exposed in C5b. The binding of C8 causes the complex to insert more deeply into the membrane. C9 binds to C8 and undergoes significant conformational changes. Not only does it acquire considerable hydrophobic character, pushing the membrane attack complex deeper into the membrane, but it also gains affinity for other molecules of C9, which polymerize into the complex. Electron microscopic studies suggest that the C5b-$9_{(n)}$ complex resembles a hollow cylinder. This cylinder is formed by the polymerized C9 molecules, which number between 12 and 18 in each complex. The C5b-8 is thought to play little active role in the structure of the cylindrical pore; it is, however, the essential catalyst for the pore's formation. The biochemical characteristics of the complement proteins are given in Table 3–2.

The Regulation of Complement Activation

Plasma Proteins

As discussed previously, the activation of the complement system is expressed as the activation of several enzymes of the serine protease group. As with any zymogen-to-enzyme conversion, there must be a way of regulating the activity of the enzyme, or else it will cleave all available substrate molecules. With the complement proteins, this regulation is achieved by multiple mechanisms. The geometric arrangement of the proteins is the simplest of these, inasmuch as several of the key enzymes function only when surface associated. The continuing activation of the complement pathway is highly dependent on the spatial arrangement of the enzyme and substrate molecules. For example, a C2 molecule associated with a C4b molecule that has been deposited more than 60 nm from the activated C1 will not be activated. Also, the enzymatic proteins of complement all occur in multisubunit or multimolecular complexes, each of which has a divalent cation requirement. The reduction of divalent cation concentration, as well as the inherent dissociation constant of the protein–protein interaction, means that the complement enzyme complexes simply fall apart.

An important way in which the body controls complement activation is through the action of specific protein inhibitors of the complement proteins. These proteins are of two sorts: plasma proteins and cellular membrane proteins (Table 3–3). Cells that are constantly exposed to the plasma milieu have evolved their own defense mechanisms against complement activation. Selective pressure to evolve defense proteins is present because the complement system does not distinguish between "good" and "bad" targets. A variety of proteins that are involved in complement regulation on cell surfaces have been described.[14]

The plasma proteins that inhibit complement work at all steps of complement activation. The only known inhibitor of activated C1 is the C1 inhibitor protein, which is also an inhibitor of kallikrein, plasmin, factor XIa, and factor XIIa. C1 inhibitor inactivates C1 by binding to the active sites of the C1r and C1s subunits with very high affinity; this binding has been suggested to be covalent. Because the C1 complex is composed of two subunits each of C1r and C1s, the inactivation of the complex requires the binding of two molecules

Table 3–3 **Characteristics of the Complement Regulatory Proteins**

Pathway	Protein	Molecular Weight (kDa)	Structure	Average Serum Concentration (mg/mL)
Activation complex classical pathway	C1 inhibitor	110	Single chain	200

N/A, not applicable.

of C1 inhibitor. Inhibition of enzymatic activity of C1 by C1 inhibitor does not modulate the ability of the C1q subunits to bind either to immunoglobulin or to specific cellular receptors for C1q.

The critical role of C1 inhibitor in the control of the complement pathway can be illustrated by the disease hereditary angioedema (HAE).[15] Approximately 80% of patients with type I HAE are shown, by both immunologic and functional assays, to have less than 50% normal levels of C1 inhibitor. The remaining 20% of patients have a normal level of a dysfunctional protein. Patients with both types of HAE are subjected to periodic attacks of acute edema that may be life threatening if there is laryngeal involvement. HAE attacks are thought to arise from minor trauma that produces localized complement activation. The ineffective regulation of C1, caused by the depletion of C1 inhibitor, results in the generation of activation peptides that induce edema. Although the exact nature of the mediators is yet to be determined, both kinin and bradykinin are candidate molecules. The levels of C2 and C4 in patients suffering HAE attacks are greatly reduced, which reflects the requirement for rapid inactivation of activated C1 to prevent substrate depletion. A similar clinical picture also arises in patients who have acquired angioedema as a result of the presence of an autoantibody reactive with C1 inhibitor. These antibodies can cause accelerated clearance of C1 inhibitor or may functionally interfere with the protein.

The other plasma proteins that regulate the classical pathway all act on the C4b2a complex. Two plasma proteins that bind C4b have been described. C4-binding protein is a multisubunit protein that circulates complexed with protein S of the coagulation system.[16] Bound protein S does not affect the complement inhibitory activity of C4-binding protein. C4-binding protein accelerates the decay of the C4b2a complex, as well as acting as a cofactor for the degradation of C4b by factor I. The other C4-binding plasma protein is a sialoglycoprotein called SGP120.[17] This molecule copurifies with C2 during C4b-sepharose affinity chromatography. It apparently is a competitive inhibitor for the C2-binding site on C4b. The precise biological role of SGP120 remains to be determined.

The plasma proteins that regulate the alternative pathway are molecules that are either inhibitory or stabilizing for the C3bBb complex. As described previously, the alternative pathway begins in the fluid phase. It is the fate of the C3b molecules deposited on the surface that distinguishes an activator from a nonactivator. The major plasma protein that regulates complement activation is factor H. The interplay between factor B and factor H, in their competition for C3b, actually determines whether a surface is "activating." On some surfaces, the binding of factor B is promoted over the binding of factor H; these surfaces are said to be activators of the alternative pathway because the C3bBb complex readily forms. If the binding of factor H is favored, the surface does not activate complement. Factor H has cofactor activity for factor I, the C3b inactivator. Factor I is a circulating serine protease that has C4b and C3b as its substrates. The degradation of C3b by factor I results in the formation of biologically important fragments of C3 that interact with specific cellular receptors. The importance of C3bBb regulation by factor H is highlighted by the manifestation of atypical hemolytic uremic syndrome in patients with diminished factor H due to congenital deficiency or the presence of autoantibody against factor H.

Although the plasma regulatory proteins just described act to downregulate the activation of complement, one protein of the alternative pathway, properdin, modulates the activity of the pathway by stabilizing the C3bBb complex. Properdin circulates in an inactive form, which becomes activated on association with C3b. Although properdin apparently binds to a site on C3b, the binding affinity increases considerably if C3b is complexed to Bb.[18]

The terminal complex of complement is regulated by two plasma proteins: vitronectin and clusterin (or Sp-40,40).

Vitronectin, the major plasma regulator of the membrane attack complex, was initially called *S-protein* by investigators in the complement field; current literature may still use this designation. This molecule is not the same as protein S of the coagulation system. Vitronectin regulates the membrane attack complex at the C5b-7 stage. When C5b-7 is formed, several molecules of vitronectin bind to the hydrophobic regions of the complex, increasing its water solubility. Inactivated C5b-7, known as SC5b-7, is capable of binding C8 and C9, but C9 polymerization is blocked. Sp-40,40 was described as an inhibitor of the membrane attack complex, which appears to act at the C5-6 level.[19,20] The protein is a disulfide-linked heterodimer; each subunit has a molecular weight of approximately 40 kDa. Sp-40,40 co-localizes with vitronectin and membrane attack complexes in tissue sections. There is some in vitro evidence to suggest that Sp-40,40 may be complexed in plasma with vitronectin. Sp-40,40 most likely shares identity with the protein clusterin, a cell-agglutinating protein that circulates in plasma complexed to apolipoprotein A-I.[21] The relative functions of this molecule in complement regulation, cholesterol transport, and cell–cell interaction remain to be determined.

Cell Membrane Proteins

Cells that come into contact with activated complement have evolved additional mechanisms to protect themselves from opsonization or cytolysis. One such adaptation is to evolve proteins that inactivate complement at the membrane surface. The analysis of such proteins has been the focus of much of the activity in complement biology since their discovery in the early 1980s.

The first such molecule described was *decay accelerating factor* (DAF; CD55), which was discovered simultaneously by two groups.[22,23] As its name suggests, DAF functions by accelerating the decay of the C3bBb or C4b2a enzyme complexes. In the alternative pathway, DAF binds to C3b, thereby disrupting the C3bBb complex. The mode of action of DAF on C4b2a is not completely clear; published studies have demonstrated the binding of DAF to both C2a and C4b.[24,25] DAF is expressed on a wide variety of tissues other than blood cells, including endothelial cells and kidney glomerular epithelial cells. The number of molecules of DAF per cell varies from 10^3 to 10^4, depending on the cell type; in addition, DAF expression in some cells can be modulated in response to mitogens and cytokines.[26] DAF has no cofactor activity for factor I inactivation of either C3b or C4b.

Membrane cofactor protein (MCP; CD46) is an integral membrane protein that regulates the C3bBb and C4b2a complexes by binding to C3b or C4b and acting as a cofactor for factor I inactivation.[27] The molecule has no decay accelerating activity. MCP acts only on C3b and C4b bound to the cell that contains the MCP; that is, it acts to regulate complement only at a very local level. The affinity of MCP for C3b is much greater than for C4b; hence its cofactor function is greater for C3b inactivation.

The third membrane protein capable of regulating complement activation at the C3 step is the complement receptor CR1 (CD35). The ligand for this receptor is C3b or C4b that is present on an exogenous cell—that is, not on the cell that bears the CR1 molecule. CR1 is an integral membrane protein with a wide tissue distribution; as discussed later, it is crucially important in the clearance of C3b-containing immune complexes from the circulation.

The plethora of proteins that have been identified as regulators of the C3/C5-converting enzymes seems at first to suggest redundancy in the complement system. However, these proteins, both plasma and membrane, act in concert to regulate complement activation in all situations in which it may arise. In the fluid phase of plasma, C4-binding protein, SGP120, and factor I control the activation of the classical pathway; factor H and factor I control the alternative pathway. The membrane proteins DAF and MCP regulate the activation of complement on autologous cell surfaces, whereas CR1 acts to regulate exogenous complement activation, particularly in immune complexes. The evolution of proteins to specifically control all activation scenarios prevents the negative physiologic sequelae of unregulated complement enzymes.

Two membrane proteins that regulate the membrane attack complex of complement by preventing the complete assembly of $C5b\text{-}9_{(n)}$ have been described.[28,29] These proteins are important in controlling the formation of membrane attack complex on cells that bear C5-converting enzyme complexes. They are also essential for protecting the cell from *reactive lysis* or *bystander lysis,* whereby the cell picks up C5b-7 from the surrounding medium even though it may not bear the C5-converting enzymes that generated the C5b-7 complex. C8-binding protein, also known as *homologous restriction factor,* is a 65-kDa protein first identified in the red blood cell membrane. It binds to C8 and prohibits the polymerization of C9 into the membrane attack complex. This protein has the characteristic of homologous restriction; that is, human C8-binding protein works best on human membrane attack complex and less efficiently or not at all with complement proteins from other species. Such species selectivity has been noted for other proteins in the complement pathway. In 1988 and 1989, four separate groups found another membrane protein that regulates the activity of the membrane attack complex.[30–33] This molecule, now known as CD59, was also called 1F5 antigen, P-18, MEM-43, homologous restriction factor 20, H-19, membrane inhibitor of reactive lysis, and MAC inhibitory factor. CD59 contains binding sites for C8 and C9 and thus appears to regulate at both C5b-8 and C5b-9.[34,35]

The regulatory proteins DAF, CD59, and C8-binding protein all belong to an unusual group of proteins that are attached to the cell membrane by a phosphatidylinositol anchor, rather than by cytoplasmic and transmembrane stretches of amino acids.[36] This anchor structure, which is synthesized in the endoplasmic reticulum, involves the attachment of a protein moiety to the phospholipid through a series of carbohydrate residues. Abnormalities in genes encoding enzymes responsible for the addition of carbohydrates to the anchor structure are associated with the development of the acquired myelodysplastic condition paroxysmal nocturnal hemoglobinuria (PNH).[36] Gene defects in PNH are clustered in the so-called *PIG-A* gene, a putative glycosyltransferase with specificity for *N*-acetylglucosamine; abnormalities often result in the complete lack of protein product. The defects in *PIG-A* gene in PNH are expressed phenotypically as the complete or near-complete absence of phosphatidylinositol-anchored proteins from the cell membrane. The lack of CD55, CD59, and C8-binding protein from PNH cells is associated with accelerated complement-mediated intravascular hemolysis and gives rise to the hemoglobinuria that is a hallmark of the disease.

Two sets of observations in other conditions suggest that it is the deficiency of membrane attack complex regulatory proteins that is responsible for the hemolytic anemia of PNH. First, it was determined by two groups of investigators that erythrocytes lacking the blood group antigens of the Cromer complex (the Inab phenotype) are deficient in DAF, the molecule that carries the Cromer antigen system.[37,38] Affected persons demonstrate no intravascular hemolysis. The second observation is a description of one patient who has a genetic deficiency of CD59.[39] This condition is associated, in this patient, with a mild hemolytic anemia and cerebrovascular thrombosis; thrombosis is the major cause of mortality in PNH. Together, these observations suggest that the regulators of the terminal complex are the most important in protecting cells from destruction by complement. The relative importance of CD59 and C8-binding protein in vivo remains to be determined.

These factors—molecular geometry, complex instability, and regulatory proteins—contribute to the marked inefficiency of the complement system. Circulating erythrocytes from a patient with cold agglutinin disease can carry over 100,000 molecules of C3 per cell; normal erythrocytes can defend themselves against as many as 20,000 membrane attack complexes. Even given the inherent inefficiency of complement, the presence of multiple regulatory mechanisms at each step of the complement pathway attests to the importance of regulating the activity of this system.

The Ontogeny and Phylogeny of Complement Proteins

The application of molecular biology to the complement system has demonstrated heretofore unidentified relationships among the proteins of complement. Many structural homologies exist within the complement system. As might be expected, structure and function are closely aligned in the complement proteins (Table 3–4). Four distinct "families" of complement proteins can be identified. The first of these is the serine protease family, which contains C1r, C1s, C2, factor B, factor D, and factor I. These proteins are related to the well-studied serine proteases trypsin and chymotrypsin. All of these proteins contain a 25-kDa protease domain at the carboxyl terminus of the protein. Because 25 kDa is the approximate molecular weight of factor D, this activator of factor B can be considered the quintessential serine protease. C1r and C1s are identical in size and contain very similar molecular features, including a set of 60–amino acid short consensus repeats (SCRs) and a type III cysteine-rich domain similar to that in epidermal growth factor. The genes encoding these two proteins are closely linked on chromosome 12 and presumably arose by gene duplication.

As indicated previously, the serine proteases of the early classical and alternative pathways are both C3/C5-converting enzymes. In addition to this functional similarity, C2 and factor B have considerable structural homology. They are similarly sized proteins composed of a single polypeptide chain; they contain similar SCRs, similar serine protease domains (shared by all serine proteases), and a region shared only by these two. The genes for both C2 and factor B lie in the class III region of the major histocompatibility complex (MHC) on chromosome 6, a region that also contains the genes for C4.

C3, C4, and C5 are highly homologous proteins. As discussed, each protein is activated by the cleavage of a small "a" fragment from the α chain of the native molecule. C3 and C4 share the feature of the reactive thiol ester bond in the α chain; this bond is lacking in C5. All three proteins are synthesized as single proproteins that undergo modification before release into the plasma to generate the two chains of C3 and C5 and the three chains of C4. Interestingly, despite the high degree of overall homology of amino acids in these proteins (about 25%), the genes for the three proteins are located on three different chromosomes: the C3 gene is on chromosome 19, the C4 genes are in the MHC on chromosome 6, and the C5 gene is on chromosome 9. Although both C3 and C5 are encoded by single genes, two genes encode C4. These genes, known as C4A and C4B, give rise to the isotypic variants of the C4 protein. On the basis of the structure of C3-like proteins in other organisms, it has been postulated that C3 arose first and C4 and C5 arose later as gene duplication products.

The terminal complement proteins (C6 to C9) also exhibit a considerable degree of homology. Each of the terminal proteins exhibits an overall amino acid homology of 18% to 33% with the other proteins. If an analysis is made considering conservative substitutions, the homology increases to more than 50%. The predominant characteristic of the terminal complement proteins is the presence of

Table 3–4 **Structural/Functional Homologies within the Complement System**

Proteins	Homology
C1r, C1s	Serine proteases with similar subunit structure Genes linked
C2, factor B	Similar size, activation Highly homologous by structure Linked in major histocompatibility complex locus
C3, C4, C5	Activation by cleavage from α chain C3 and C4 contain reactive thiol ester Amino acid sequences show >20% overall identity
C6, C7, C8, C9	Share overall homology to one another ranging from 16% to 33% C6 and C7 share greatest homology All undergo amphipathic conversion to acquire membrane-binding character
CR1, CR2, factor H, DAF, MCP, C4 binding protein	All function to regulate complement activation All have multiple (60–70) amino acid short consensus repeats

DAF, delay accelerating factor; MCP, membrane cofactor protein.

cysteine-rich regions. From the amino terminus, using the nomenclature of Morgan,[2] the four types of cysteine-rich domains are known as type I, type II, type III, and the SCR (Fig. 3–2). The terminal complement proteins all contain type I cysteine-rich domains of approximately 60 amino acids, as well as other cysteine-rich domains of approximately 40 amino acids that share sequence homology to those in the low-density lipoprotein receptor (types II and III). These cysteine-rich domains, which greatly contribute to the tertiary structure of the protein, are clearly important for function. The SCRs are present in at least 12 of the complement proteins, and 8 proteins contain the other types of cysteine-rich domains. C6, C7, and C9 are single-polypeptide chains encoded by single genes; C8 is composed of three polypeptide chains, each of which is encoded by its own gene. The C8 α and β proteins are highly homologous, but the C8 γ chain shows no homology to any complement protein; it shows homology to α_1-microglobulin.

The proteins involved in the regulation of complement activation are also structurally related. In addition, the genes encoding the proteins that modulate C3 and C4 activation are grouped in one region of the long arm of chromosome 6 known as the *regulators of complement activation* (RCA) cluster.[40] The RCA group includes factor H, C4-binding protein, DAF, MCP, and the complement receptors CR1 and CR2. These proteins contain a variable number of SCRs of 60 to 70 amino acids. The chromosomal assignments of the complement proteins are given in Table 3–5.

Molecular biology has also proved invaluable in the identification of polymorphisms of complement proteins that had previously been noted as variants in electrophoretic mobility or antigenicity. Polymorphisms have been described for most of the complement proteins.[41,42] Some of the complement protein polymorphisms are associated with a loss or decrease of complement activity. Others demonstrate some degree of disease association; however, no disease associations have been established for any polymorphisms of the terminal complex proteins.

THE PHYSIOLOGIC RESPONSE TO COMPLEMENT ACTIVATION

Anaphylatoxins

The cleavage of C3, C4, or C5 by the enzyme complexes of the alternative or classical pathways results in the formation of two fragments. The fate of the C3b, C4b, and C5b fragments was discussed previously. The other fragments, C3a, C4a, and C5a, are known as the *anaphylatoxic fragments of complement*. These very small fragments of complement can produce a very large and potentially life-threatening physiologic response. The C3bBb and C4b2a enzyme complexes recognize an Arg-X sequence near the amino terminus of C3, C4, and C5. Cleavage of this bond results in the formation of a small N-terminal peptide of 77 amino acids for C3a and C4a and a small N-terminal peptide of 74 amino acids for C5a, each with a C-terminal arginine residue.

Although these peptides are very similar in structure, their potency in mediating cellular responses varies considerably. C5a is the most potent of the complement-derived anaphylatoxins, and C3a is the least potent. These complement fragments exert their anaphylatoxic effects by interacting with specific cellular receptors present on the surface of mast cells and basophils. The occupation of the receptor triggers the release of histamine and serotonin from intracellular granules. These two soluble factors cause contraction of smooth muscle cells and increased vascular permeability of blood vessels. Neutrophils, monocytes, macrophages, and platelets also bind anaphylatoxic fragments of complement; the occupation of these receptors activates the cell and, in the case of neutrophils, induces chemotaxis toward the site of complement activation.

Although the anaphylatoxic fragments of C3, C4, and C5 are potent biological response modifiers, they are rapidly inactivated in plasma by the action of a pair of carboxypeptidases. The best known, serum carboxypeptidase N, removes the C-terminal arginine residue from the peptide. Another

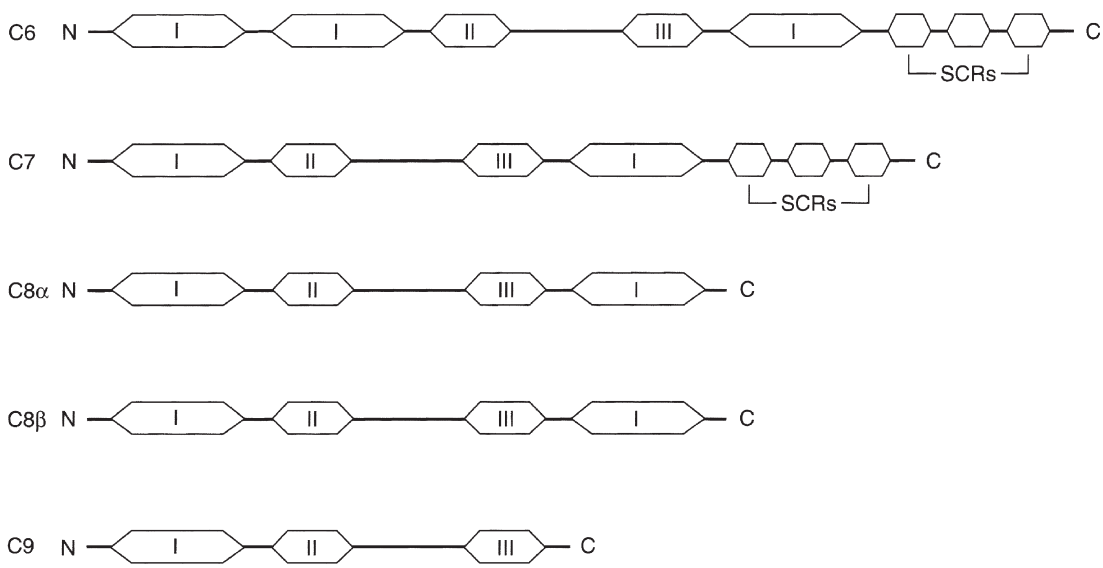

Figure 3–2 The domain structure of the terminal complex proteins. This figure illustrates the relative homologies among the proteins of the membrane attack complex. The highly homologous regions are found within cysteine-rich domains types I, II, and III (according to Morgan[2]). In addition, C6 and C7 contain cysteine-rich short consensus repeats (SCRs). (From Anderson KC, Ness PM. Scientific Basis of Transfusion Medicine, 2nd ed. Philadelphia, Saunders, 2000.)

Table 3–5 **Chromosomal Assignments of the Complement Proteins**

Protein(s)	Chromosomal Assignment
C1q	A, B and C chains on 1
C1r/C1s	Closely linked on 12
C2, C4A, C4B, factor B	In MHC locus on 6
C1 inhibitor, CD59	11
C4-binding protein, factor H, CR1, CR2, MCP, DAF	In RCA cluster on 1
Factor D	19
Factor I	4
Properdin	X
C3	19
C5	9
C6/C7	Closely linked on 5
C8	α and β chains on 1; γ chain on 9
C9	5

DAF, delay accelerating factor; MCP, membrane cofactor protein; MHC, major histocompatibility complex; RCA, regulators of complement activation.

enzyme, carboxypeptidase R, has been identified as the primary inactivator of kinin as well as anaphylatoxin peptides.[43] Unlike carboxypeptidase N, carboxypeptidase R is itself rapidly inactivated under normal purification conditions. After removal of the arginine, the peptide acquires the designation "des arg." C3a and C4a are rapidly and completely inactivated by the two carboxypeptidases; C5a is somewhat more resistant to inactivation. In addition, neutrophils can still respond to C5a des arg, albeit with some 10^3 weaker affinity; the removal of arginine from C3a and C4a results in complete loss of biological activity.

The relative resistance to carboxypeptidases and retention of bioactivity make C5a the most physiologically important of the anaphylactic complement peptides. Generation of C5a causes many of the effects seen in inflammation that are mediated by neutrophils. After activation by the binding of C5a into specific receptors, neutrophils bind to the capillary endothelium and migrate through the vessel wall, after the concentration gradient of the C5a. Once they are in contact with the higher concentrations of C5a present at the site of complement activation, neutrophils release granule contents and reactive metabolites, including lysozyme, reactive oxygen species, and eicosanoids. Although this is part of the normal mechanism of response to tissue injury or infection, the generation of large amounts of C5a or its presence in inappropriate locations can cause significant damage to uninvolved tissues.

Other Complement Activation Peptides

Other peptides generated during the course of complement activation have been identified as inducing cell activation or chemotaxis. Factor Ba, the peptide cleaved from factor B by factor D, is a weak chemotactic factor. The cleavage products of factor B—Ba and Bb—have been reported to inhibit and stimulate B-cell proliferation, respectively. Peptides with functions similar to those of C3a and C5a can be generated by the action of noncomplement enzymes, particularly plasmin, on C3 and C5. These C3a-like and C5a-like peptides may play a role in the activation of both platelets and white cells under existing blood storage protocols. The use of negatively charged leukoreduction filters may significantly affect the levels of various contact activation peptides in blood products.[44] In general, negatively charged artificial membrane surfaces promote complement activation; however, some types of filters appear to remove C3a that is generated during processing and storage.[45]

The membrane attack complex itself causes significant activation in a wide variety of cell types. Because most studies of the C5b-9 complex have focused on its lytic effect on erythrocytes, the functional effect on nucleated cells and platelets has lately gained appreciation. Although there are some reports in the literature that C5b-7 has chemotactic activity for neutrophils, it is the fully formed C5b-9 that has the greatest effect on these cells. In comparison with erythrocytes, nucleated cells are very resistant to C5b-9 lysis. In response to C5b-9, nucleated cells and platelets coalesce the C5b-9 complexes and bud them off in vesicles of plasma membrane. In nucleated cells, especially neutrophils, this process is accompanied by the activation of the cell and the release of enzymes, leukotrienes, prostaglandins, thromboxanes, and reactive oxygen metabolites from the cell.[46]

Platelets interact with the activated proteins of the complement system at several levels.[47] Specific platelet receptors for C1q have been identified.[48–50] Although the precise role of C1q receptors remains to be determined, one such receptor has been reported to play a role in phagocytosis in other cell types.[51] The exposure of human platelets to C3a alters the response to physiologic agonists but does not induce platelet aggregation. The effect of C5a on human platelets has not been investigated. Membrane attack complex can also affect platelet function.[52] C5b-9 can induce the formation of platelet membrane vesicles (or microparticles), increase the procoagulant activity of the platelet, and cause some degree of arachidonic acid generation.[53] Studies of the effects of C5b-9 on platelets have been carried out in purified protein systems; the significance of these observations for the whole plasma system remains to be determined. The platelet may modify the effects of activated complement fragments through the action of its surface regulatory proteins, DAF, MCP, C8-binding protein, and CD59. Platelets also contain internal pools of vitronectin, which may contribute to the local modulation of complement. The significant effects of activated complement fragments on the physiologic processes of platelets must be considered in the setting of platelet concentrate storage. Complement is activated under storage conditions,[54] with or without prestorage leukoreduction. Activated complement fragments as well as C5b-9 may contribute to the platelet storage lesion.[55]

EFFECTS OF COMPLEMENT ACTIVATION ON CELL SURVIVAL

Cytotoxic Effects

In the transfusion medicine setting, the effects of complement activation are graphically illustrated by the acute intravascular transfusion reaction. The generation of C3a and C5a produces bronchospasm and hypotension. C5a can also stimulate the production of interleukin-1 from macrophages, thereby causing fever.[56] The recruitment of large numbers of neutrophils to the lung by C5a generation produces ventilation–perfusion abnormalities. This effect may have devastating consequences for the recipients of transfusion products who develop TRALI subsequent to the fixation of complement by anti-HLA antibodies. Two other hallmarks of the acute intravascular transfusion reaction, hemoglobinemia and hemoglobinuria, result from the activation of complement on the red cell surface in sufficient amounts to overwhelm the cellular and plasma control proteins, thereby lysing the cell. The generation of activated complement proteins affects more than red cell survival. The activation of cells with the concomitant release of enzymes contributes to the activation of the coagulation system, as does the action of complement proteins on coagulation substrates and endothelial cells. In vitro studies suggest that these processes may trigger the disseminated intravascular coagulation seen in severe cases of hemolytic transfusion reaction. Evidence for the direct cytolysis of platelets or granulocytes during transfusion is not abundant, perhaps because of the difficulty in constructing an adequate study design. However, complement activation may be directly linked to platelet destruction in the setting of paroxysmal nocturnal hemoglobinuria, sepsis, and thrombotic thrombocytopenic purpura/hemolytic uremia syndrome. Each of these conditions is associated with complement activation and platelet dysfunction. The complement-mediated destruction of antibody-coated platelets can be experimentally induced. Antibody to the human platelet antigen $P1^{A1}$ (HPA-1) fixes sufficient complement to lyse target platelets.[57] In vitro platelet lysis can also be induced by cold agglutinin anti-I antibodies[58]; antibodies of this specificity have been proposed to mediate the thrombocytopenia associated with Epstein-Barr virus infection.

Opsonic Effects

The opsonic effects of complement activation result in the accelerated clearance of particles or cells that bear C3 as well as IgG. Although complement activation is the primary mechanism of cell destruction in the acute hemolytic transfusion reaction, the extravascular destruction of erythrocytes does not have the absolute requirement of complement activation. The primary clearance mechanism is through the phagocyte Fc receptor with recognition of the IgG present on the cell surface.[59] Opsonization of cells by complement, rather than through lysis, means that the cell has been able to regulate complement effectively to prevent the assembly of cytolytic membrane attack complexes. This regulation may reflect the titer, avidity, affinity, or thermal amplitude of the antibody in its interaction with the cell target.

In addition, as described previously, only IgG1 and IgG3 are efficient complement activators. The presence of C3b (or its degradation products) on the cell target in addition to antibody accelerates the clearance by the reticuloendothelial system. If a macrophage is already activated, it will bind and ingest cells that bear only C3b. Normal, resting macrophages require that IgG also be present on the erythrocyte surface. This experimental result is supported by the in vivo observation that the erythrocytes of patients with cold agglutinin disease circulate through the spleen bearing C3b but no IgG and are not sequestered. That is not to say that C3 has no in vivo role in clearance. Bacteria coated with C3 only are efficiently phagocytized by macrophages, resting or activated, even in the absence of IgG. Macrophages in the liver (Kupffer cells) are capable of clearing erythrocytes coated with C3b only. In addition, persons who are genetically deficient in one of the components of the early classical pathway are unable to bind C3 to anti-D-coated erythrocytes; those target cells are cleared from the circulation much more slowly than in persons with intact complement systems.[60]

The opsonic and cytotoxic effects of complement are important in the ex vivo setting of blood storage. Many types of bacteria that have been implicated in transfusion-mediated sepsis are either lysed or opsonized by the complement proteins in the blood unit. These bacteria are then engulfed by phagocytes also present in the bag. The removal of phagocytes by leukodepletion within 24 hours of collection results in the removal of contaminating bacteria as well. Leukodepletion more than 24 hours after collection may fail to sterilize the unit, because white cell breakdown may result in the release of viable bacteria from phagolysosomes.

The Role of Complement Receptors in Cell Clearance and in Maintenance of the Immune Response

The removal of complement-coated target cells is mediated by specific receptors for C3 and its activation and degradation fragments. As previously discussed, the activation of C3 produces two fragments, C3a, the anaphylatoxin, and C3b, which is covalently bound to the cell surface. In the presence of factor H, MCP, or the complement receptor CR1, C3b is rapidly cleaved by factor I to an inactivated form, iC3b (Fig. 3–3). This cleavage is estimated to occur in vivo within 5 minutes of the generation of C3b. Inactivated C3b undergoes another, slower interaction with factor I that results in a second cleavage on the opposite side of the thiol ester bond from the initial cleavage. This second cleavage occurs within 30 minutes of generation of C3b and results in the generation of the C3c fragment, which is no longer tethered to the cell, and the C3dg fragment, which contains the thiol ester bond and remains bound to the cell surface. Under laboratory conditions, the C3dg fragment can be further cleaved by trypsin to leave the C3d fragment on the cell surface; the frequency of generation of this fragment in vivo is uncertain.

Several complement receptors have been identified to date. They have overlapping cell distribution (Table 3–6). The specificity of these receptors for individual fragments of C3 is reflected in the biological response to receptor occupation. The central function of the complement receptor CR1 is clearance of immune complexes from the circulation through its interaction with C3b contained in the complex.[61] The bulk of the total CR1 in the circulation is present on red cells, because they provide the greatest mass of cells in the peripheral blood. The erythrocyte is therefore essential in transporting immune complexes from the plasma to the resident macrophages in the spleen.

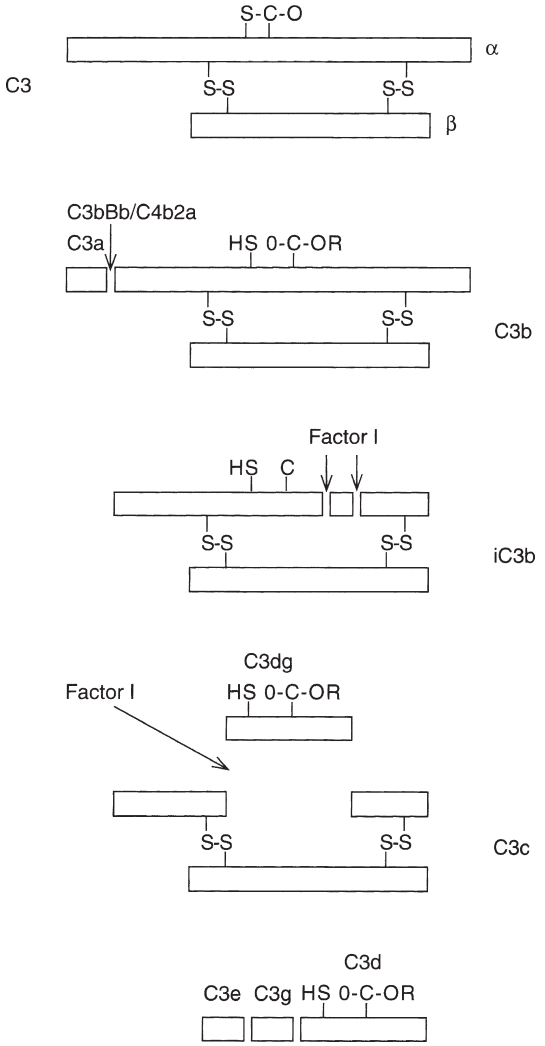

Figure 3–3 Degradation fragments of C3. Native C3 is cleaved by C4b2a or C3bBb, resulting in the exposure of a reactive thiol ester in the α chain of C3 and the generation of two fragments, C3a and C3b. C3b is inactivated by factor I in the presence of factor H or CR1 to iC3b, which remains bound to the surface by the thiol ester. A further cleavage by factor I on the other side of the covalent bond from the first cleavage results in the release of the C3c fragment; the C3dg fragment remains surface bound. In vitro, the C3dg fragment may be further degraded to C3d, C3e, and C3g. The C3d fragment, a terminal breakdown product of C3, remains covalently bound to the surface. (From Anderson KC, Ness PM. Scientific Basis of Transfusion Medicine, 2nd ed. Philadelphia, Saunders, 2000.)

The further processing of C3b to iC3b enables the complement fragment to interact with the complement receptor CR3, also known as CD11b/CD18. This receptor, with its distribution on monocytes, macrophages, and neutrophils, plays a major role in immune-mediated phagocytosis. CR3 belongs to a family of related receptor molecules that have the β chain CD18. The pairing of the CD11a α chain to CD18 defines the leukocyte function-associated antigen 1, which is important in mediating killing by T lymphocytes. CD18 may also pair with the α chain CD11c, forming the complex known as p150,95. This molecule has been unofficially designated CR4 in recognition of its binding affinity for iC3b.

The importance of the complement receptors CR3 and CR4 is indicated by the severity of the deficiency state, in which patients have defective phagocytic function and are susceptible to recurrent infections.[62] The degradation of iC3b by factor I produces C3dg, the principal ligand for the receptor CR2. The expression of CR2 is restricted to B lymphocytes, on which the binding of C3dg triggers B-cell activation and proliferation. In addition to its role as a C3dg-binding protein, CR2 is the cellular receptor through which the Epstein-Barr virus gains entry to B lymphocytes. The identification and characterization of the complement receptors has led to the development of new therapeutic modalities. For example, a recombinant CR1 has been engineered with the transmembrane region missing. This molecule retains the complement-regulatory ability of CR1 but is soluble in plasma. In animal models, this protein, sCR1, has proved efficacious in reducing the complement activation seen during thrombolytic therapy.[63]

Fragments of C3 are important in maintaining the immune response.[64] Animals with an experimental depletion of C3 fail to mount a normal IgG response to secondary immunization. This observation suggests that C3 is important in the development of immunologic memory, but such a role for C3 has not been confirmed in humans. It has also been established that the complement receptors CD21 and CD35 are important in the regulation of B-cell immunity while the complement regulatory proteins CD46 and CD55 have an additional role in T-cell function through the regulation of cytokine production.[65,66]

Therapeutic Complement Inhibition

The great advances in our understanding of both complement system biochemistry and the role of complement in

Table 3–6 **Structure and Distribution of Complement Receptors**

Receptor	Molecular Structure	Cellular Distribution
C1q	65 kDa, single chain	Platelets, monocytes, macrophages, B lymphocytes, endothelial cells
C3a	Single chain protein predicted to have 7 transmembrane regions	Mast cells, monocytes, macrophages, neutrophils, basophils, T cells
C5a	45 kDa, single chain	Monocytes, macrophages, neutrophils, mast cells
CR1 (CD35)	Four allotypes ranging from 160 to 250 kDa	Erythrocytes, monocytes, neutrophils, B lymphocytes
CR2 (CD21)	145 kDa, single chain	B cells, follicular dendritic cells
CR3 (CD11b/CD18)	Two chains, 165 kDa and 95 kDa	Neutrophils, monocytes, macrophages, follicular dendritic cells, natural killer cells
CD11c/CD18 (CR4)*	Two chains, 150 kDa and 95 kDa	Neutrophils, monocytes, macrophages, natural killer cells
(CR5)*	Unknown	Neutrophils, platelets

*CR designation is unofficial.

pathophysiology have led to the creation of strategies to control complement activation in order to minimize its deleterious effects.[67] Several promising compounds are in preclinical development; one monoclonal antibody against C5 has been used successfully in a clinical trial in the treatment of PNH to reduce ongoing hemolysis.[68] Although complement inhibitors have been proposed for use in acute hemolytic transfusion reactions, no clinical studies have yet been performed.[69]

LABORATORY ANALYSIS OF COMPLEMENT

Measurement of Cell-Associated Complement

The methods available for the measurement of cell-associated immunoglobulins are readily adaptable to the detection of cell-bound complement. Traditionally, the presence of cell-associated C3b and its cleavage products is *detected* by means of an aggregating anti-C3d antibody (C3 Coombs' test). The presence of small amounts of C4d antigen on the erythrocyte is identified in the blood bank as the Chido-Rodgers blood group antigen system. The antigenic difference is actually determined by the C4A and C4B alleles, with Rodgers specificity found in the C4A isotypes and Chido specificity found in the C4B isotypes. Techniques developed to measure cell-associated immunoglobulin can all be adapted to measure cell-bound complement, especially C3. These methods include fluorescence flow cytometry, radioimmunoassay, and enzyme-linked immunosorbent assay (ELISA).[70,71] In addition, the development of monoclonal antibodies that can distinguish among the various fragments of C3 may prove useful in laboratory diagnosis.

Measurement of Complement Activation or Deficiency States

Until the mid-1980s, there were no readily accessible tests of complement activation. The activation of complement was implied by a decrease in the level of an individual component, most often C4, in a clinical setting in which activation was suspected. Although this approach may be of some utility in the outpatient setting, it is of little use in the investigation of very sick patients, especially those receiving blood products. The problem with this diagnostic approach is twofold. First, reduction in the C4 level can occur from decreased synthesis of the protein in the liver rather than from consumption. Second, because of the presence of null genes for C4, the normal range for C4 is very wide; a person with a C4 level that usually is at the high end of the normal range may activate more than 50% of C4 before the measured level exceeds the normal range. Only laboratories with specialized complement expertise had methods permitting the detection of activation peptides of complement, generally by gel electrophoresis techniques or by radioimmunoassay of small complement fragments remaining in solution after precipitation of native protein and large fragments.

With the advent of monoclonal antibody technology, antibodies have been made that are capable of recognizing neoantigens expressed in the activation peptides of complement. These antibodies have been used in the formulation of commercial ELISA kits. ELISA tests that detect the activation peptides of either the classical (C4d) or alternative (factor Bb) pathway or both (C3a, C5a, iC3b, and C5b-9) are currently available. In addition, descriptions of many other monoclonal antibody-based activation peptide assays can now be found in the literature. These activation-dependent assays enable definite differentiation between patients with complement activation and those with decreased production of complement proteins.

Until recently, the assessment of patients with suspected complement deficiencies has relied on somewhat cumbersome gel methods. However, a new ELISA-based procedure has been developed for detection of complement deficiencies, including those due to a loss of proteins in the lectin pathway.[72] The continuing improvement of testing methods should make these assays more accessible to nonspecialists.

In summary, the burgeoning of research activity on the complement system has produced a clearer understanding of the biochemistry of these important proteins. This knowledge has led to the development of better diagnostic tools, to an increased clarity around the role of complement in disease pathophysiology, as well as to the invention of therapeutic modalities to control unwanted complement activation.

Chapter 4

Principles of Red Blood Cell Allo- and Autoantibody Formation and Function

James C. Zimring

INTRODUCTION

Humoral immunity represents the main barrier to transfusion of red blood cells (RBCs) in humans. Crossmatching units of RBCs for the naturally occurring antibodies against the ABO carbohydrate antigens is an absolute requirement to avoid acute hemolysis. However, the majority of immunohematology focuses on the identification of acquired antibodies to RBC antigens, which are typically generated after previous exposure to foreign RBCs. Several hundred different RBC antigens have now been described (see Chapters 5, 6, 7, and 8). These antigens can consist of carbohydrates, linear peptides, and tertiary confirmations dependent on proper folding and membrane insertion. Different blood group antigens have distinct immunogenicities, because RBC antigens vary in their likelihood of inducing an antibody response. In addition, antibodies to some blood group antigens frequently cause hemolysis (clinically significant), whereas others cause no deleterious effect (clinically insignificant). The current understanding of the basic science regarding immunogenicity of transfused RBCs and the immune-mediated mechanisms of RBC destruction are detailed in this chapter.

BASIC SCIENCE OF ALLOANTIBODY FORMATION

Most anti-RBC antibodies detected in the practice of transfusion medicine are humoral responses to alloantigens encountered during previous exposures to foreign RBCs, typically via transfusion or pregnancy. A great deal is now understood about the general mechanics of humoral immunization to soluble and particulate antigens (see Chapter 2). However, although sheep red blood cells have been used as a model antigen for many years, the current paradigms of immunology have been largely developed outside the context of immunization by RBC transfusion. Transfused RBCs appear to be only weakly immunogenic, and it is currently unclear if immune responses to RBC transfusion are qualitatively different from general mechanisms of immune response to foreign antigen. However, it is safe to say that there are several notable differences between traditional microbial or protein immunogens and transfusion of sterile blood, including route of immunization, potential absence of inflammation and danger signals, dose and kinetics of antigenic exposure, type of antigen-presenting cell involved, and the molecular nature of the antigen. The exact role and importance of these variables in RBC transfusion is currently unknown, but the theoretical potential for their importance is discussed in the following sections.

Frequency of Alloimmunization to RBC Transfusion: Immunity and Tolerance

Despite there being numerous foreign epitopes on essentially all transfusions of nonautologous RBCs, transfusion is not a highly immunogenic stimulus. Even in response to multiple transfusions, alloimmunization to alloantigens on transfused RBCs has an overall frequency of approximately 2% to 6%.[1–3] However, it has been hypothesized that frequency of alloimmunization may vary with the underlying pathophysiology of the transfused patient. One study revealed alloimmunization rates as follows, based on underlying disease: lymphocytic leukemia 0%, gastrointestinal bleed 11%, aplastic anemia 11%, renal failure 14%, myelogenous leukemia 16%, and hemoglobinopathy 29%.[4] These findings indicated a trend, with a clear decrease in lymphocytic leukemia, presumably due to immunosuppression. There is also an apparent increase in other disease states, but these differences were not found to be statistically significant.

It has been proposed that alloimmunization is unusually high in some disease states, such as sickle cell anemia, myelodysplastic anemia, and autoimmune hemolytic anemia. However, rates of alloimmunization can vary widely from study to study. For example, the range of alloimmunization in adult sickle cell patients ranges from 18.6%[5] to 47%,[6] depending on the study, with an average rate of 25%.[7] The presence of alloantibodies in patients with autoimmune hemolytic anemia, when excluding autoantibodies that mimicked alloantibodies, ranges from 12%[8] to 40%,[9] with an average frequency of 32%.[10] Likewise, two different groups reported alloimmunization rates in patients with myelodysplastic syndrome as 21% and 58.6%, respectively.[11,12]

Analysis of the above literature demonstrates considerable variation in the rates of alloimmunization reported by different groups. A number of factors may lead to varying results, including differences in patient demographics, differences in diagnostic criteria or subclasses of disease, and differences in methodology of alloantibody detection. In addition, it has been reported that up to 40% of alloantibodies subsequently become undetectable,[13,14] raising the possibility that the time after transfusion that specimens are collected may influence outcome. It has also been reported that leukoreduction may decrease immunogenicity of transfused RBCs.[15] Since use of leukoreduced blood varied in the above studies, this may be

a relevant issue. A further complicating factor is that most studies are retrospective and do not compare pretransfusion specimens to post-transfusion specimens and it is unclear if the presence of an alloantibody is necessarily the result of an antecedent transfusion.

The precise mechanism by which different patient populations may differ in their alloimmunization rates is unclear. However, a number of potential factors may be involved. First, the volume and frequency of transfusion are important variables, because they reflect the magnitude and kinetics of antigen dose. Second, the extent to which donor units differ phenotypically from recipient RBCs will always be an important factor. Thus, one must consider the genetic similarity of the donor and recipient populations. A third variable is the extent to which the underlying pathophysiology of the condition necessitating transfusion may perturb immune function. For example, systemic immunosuppression linked to the pathophysiology likely contributes to a low rate of seroconversion in patients with lymphocytic leukemia.[4] In contrast, the pathophysiology of other disease states may lead to immune dysregulation resulting in increased alloimmunization.

Given that only a small percentage of individuals make detectable alloantibodies, despite multiple transfusion, it appears as though RBCs may represent a fairly weak immunogen. Of course, this notion is biased by the fact that RBCs are typically matched a priori for the most immunogenic antigens (i.e., Rh_0D). Immunization rates to Rh_0D have been estimated at 30% to 90%,[16–23] depending on the study. Still, even for the Rh_0D antigen, up to 20% of Rh-negative individuals do not mount an anti-Rh response, despite repeated exposure to Rh-positive blood. The nonresponse of such individuals may in part be due to Rh actually being self in the case of recipients who are weak D and do not type D+ by routine methods. In addition, nonresponders may have genetic factors such that they lack the ability to respond to the Rh antigen. However, this pattern is also consistent with initial exposure to Rh-positive RBCs inducing a state of active tolerance against Rh antigens, although such has not been demonstrated. Thus, overall, transfused RBCs are strongly immunogenic in some recipients, only weakly immunogenic or nonimmunogenic in other patients, and the theoretical potential for tolerance exists.

VARIABLES ASSOCIATED WITH RBCs AS AN IMMUNOGEN

The context in which the immune system encounters antigens on transfused RBCs is associated with a number of characteristics that may contribute to the relatively weak immunogenicity of RBCs in some settings.

Route of Immunization

Unlike subcutaneous and intramuscular routes, which are generally immunogenic, intravenous administration is among the most tolerogenic methods of antigen administration.[24–26] Because transfusion of a sterile unit of RBCs involves introduction of intravenous antigen, one might predict that no immune response should occur to RBC antigens. However, the induction of tolerance to intravenous antigen has typically been described with soluble proteins, and aggregated protein complexes are typically immunogenic. Although blood group antigens are polymeric as a result of being in a membrane, the molecules that carry blood group antigens are neither free-floating soluble proteins nor are they insoluble protein aggregates. Thus, it is unclear how this molecular form fits into the paradigm of soluble versus aggregate. It is worth noting that although intraperitoneal injection of soluble protein is not immunogenic, injection of the same protein chemically coupled to autologous RBCs results in an antibody response equivalent to immunization with the antigen in Freund's complete adjuvant, which is among the strongest known methods for immunization.[27,28] The same observation has recently been made regarding both humoral and cellular immunity using the intravenous route.[29,30] Thus, the intravenous route through which blood is given may influence the immunogenicity of antigens on RBCs, but the particulars of this are unclear given the form in which the immune system encounters RBC antigens.

Absence of a Danger Signal

It has been argued that without an inflammatory stimulus (also called a *danger signal*), immunity will not typically occur.[31,32] Danger signals are not present on healthy self-tissues and typically need to be introduced by microbial infections or inflammation.[33–37] In support of this concept, even a subcutaneous injection into the footpad of mice, which is typically the best route to induce humoral immunity, can induce tolerance when performed in the absence of an inflammatory adjuvant.[24] Properly processed units of RBCs should not contain any microbial products. However, it is possible that processing and transfusion of blood introduces danger signals from nonmicrobial sources. It is also possible that the danger signal is provided by ongoing inflammation in the transfusion recipient. Thus, the role of inflammation and/or danger signals during RBC transfusion is unclear. However, whereas danger signals would be typically present during infection and immunization, they may be altered or absent during transfusion, which could influence the nature of anti-RBC immune responses.

Dose of Antigen

Another important difference between an RBC transfusion and other immune stimuli is the amount of antigen present. The dose of foreign antigen received during the early stages of an infection can be quite low, especially when the infection begins as a small inoculum. As the infection proceeds, levels of antigen will rise rapidly and then decline within several weeks in the case of adequate clearance. Alternatively, in a chronic infection, the antigen will often still decline, but will persist at some level long term. In contrast, transfusion of blood results in a sudden burst of high-level antigen that persists for a moderate period of time (several months).

In the case of fresh blood, transfused RBCs have a life span of approximately 120 days. Starting with a transfusion of a single 200-mL unit of packed RBCs, approximately 1.67 mL of packed RBCs are consumed per day, which translates to consumption of about 12.8 million RBCs per minute. Because these cells are removed by macrophages of the reticuloendothelial system, RBC transfusion essentially represents a selective targeting of large doses of foreign antigen to professional antigen-presenting cells (APCs). Transfusion of a stored unit of blood will result in a slightly different pattern of consumption, because RBCs continue to senesce during storage of blood products.[38] Transfusion of a 200-mL bag of blood that has been stored for 4 weeks may result in more

rapid removal of packed RBCs due to senescence of stored blood.[38] Thus, in contrast to the patterns seen with infectious pathogens, transfusion of RBCs results in a sudden introduction of large amounts of antigen (or very large amounts in the case of stored blood), followed by persistence of the antigen for several months. In the case of chronically transfused patients, exposure to common blood group antigens may be extended to a considerably longer period of time, depending on the frequency of transfusion.

Dose alterations can profoundly affect immune responses. It has been known for decades that moderate doses of antigen generally promote immune responses, whereas both low levels and very high levels of antigen lead to tolerance.[39] Duration of antigen persistence also has a significant effect on the nature of the immune response. Although $CD4^+$ T cells expand and differentiate into helper T (Th) cells on initial exposure to antigen, extended exposure to antigens during chronic infection results in the inactivation and downregulation of viral antigen-specific $CD4^+$ T cells.[40,41] Moreover, the level of antigen present during chronic exposure can regulate immunity versus tolerance at the level of $CD4^+$ Th cells.[42]

Antigen-Presenting Cells Involved in Processing and Presenting RBC Antigens

In order for a primary immune response to occur, a professional APC (typically a macrophage or dendritic cell) must process and present the antigen. Although macrophages are not required for immune responses to antigens in tissues,[43–45] evidence suggests that they are necessary for generating immune responses to transfused RBCs.[43–45] Thus, the type of APC required for a primary immune response to transfused RBCs may differ from the APC required for responses to other better-studied antigens.

Evidence also suggests that the lymphatic compartment, and thus the immunologic microenvironment, varies for antigens injected into tissues and transfused RBCs. Tissue-injected antigens are consumed by resident dendritic cells, which then migrate to draining lymph nodes and accumulate in areas of naive T-cell activation, whereas macrophages are excluded from these areas.[44] Likewise, lessons can be learned from solid tissue transplantation, where immune responses can be generated via two mechanisms. The direct pathway involves donor dendritic cells migrating to recipient lymph nodes and priming recipient T cells. In the indirect pathway, however, recipient dendritic cells enter the transplanted tissues, consume donor antigens, and return to recipient lymph nodes to prime T cells with donor antigens on recipient MHC. In both cases, the predominant APC is a dendritic cell in the specialized microenvironment of a lymph node. In contrast, the majority of transfused RBCs are consumed by macrophages in the spleen and liver, and there is no discrete tissue parenchyma where recipient dendritic cells can enter.

Polymeric Nature of Antigens on RBCs

Erythrocyte surface antigens are physically linked via their mutual association with the cellular membrane and are thus polymeric in nature. As a group, polymeric antigens tend to be T-cell independent antigens that directly activate B cells[46] to secrete immunoglobulin M (IgM) without the requirement of T-cell help. However, responses to T-cell independent antigens typically fail to class switch to high-affinity IgG. Thus, it is possible that transfused RBCs activate T-cell independent pathways of humoral immunization. In support of this notion, it has been shown that initial anti-RBC IgM responses can be T-cell independent.[46] However, in animal models, subsequent class switching to anti-RBC IgG depends on T-cell help.[46] In addition, human patients with defective helper T-cell function secondary to infection with human immunodeficiency virus have significantly decreased rates of alloimmunization to transfused RBCs.[47] Thus, as an immunogen, RBCs appear to have a unique combination of early T-cell independence for IgM synthesis followed by T-cell dependence for class switching and memory.

BASIC SCIENCE OF ANTI-RBC AUTOANTIBODY FORMATION

Loss of immunologic tolerance to self-tissues can result in autoimmune processes targeted against specific organs or broadly reactive with self-tissues. Among the known autoimmune pathologies is the generation of autoantibodies against self-RBC antigens. This process can result in a clinically silent autoagglutinin that is detected incidentally by a positive direct antiglobulin test (DAT) during alloantibody screening. However, if the autoantibodies promote erythrocyte destruction, the clinical manifestation of autoimmune hemolytic anemia (AIHA) can result. AIHA can range in severity from a transient mild clinical course to massive lethal hemolysis. Although the exact etiology of AIHA is unclear, it can occur either spontaneously or in close temporal association to transfusion of RBCs. Because the basic processes that lead to AIHA in these two settings are likely different, they are considered separately in the following discussion.

AIHA Not Associated with a Transfusion (Spontaneous AIHA)

Although the loss of tolerance to self-tissues is a general feature of all AIHA, it is unlikely that a single mechanism accounts for the process by which anti-RBC autoantibodies are generated. In the general field of autoimmune pathophysiology, a number of mechanisms may explain how loss of self-tolerance occurs. Because there is evidence for several of these mechanisms playing a potential role in the generation of AIHA in different settings, each will be considered here.

Central and Peripheral Tolerance to Blood Group Antigens

The fine-tuning of the immune system such that it can respond to a wide variety of microbial antigens without recognizing self-tissues is essential to both maintaining immune competence and avoiding autoimmunity. The process begins when T-cell receptors and B-cell receptors recombine randomly and generate a highly diverse repertoire of specificities. Then, in a process referred to as *central tolerance,* immature autoreactive T cells are deleted in the thymus, and autoreactive B cells either become anergic or are deleted, first in the bone marrow and then in the periphery. Such deletion events depend on the exposure of these lymphocytes to self-antigens during development. Although a great variety of antigens are expressed in the thymus, and the majority of autoreactive T cells are deleted, some autoreactive T cells escape this thymic education.

If RBC-specific T cells and B cells survive deletion, AIHA could develop. This theory has been formally demonstrated

in an animal model. In the NZB mouse, which spontaneously develops AIHA, $CD4^+$ helper T cells specific for peptides from RBC autoantigens survive thymic education, whereas in other strains that do not develop AIHA, the cells are deleted.[48] Moreover, it has recently been shown that autoreactive T cells specific for peptides from Rh antigens are detectable in human patients with measurable anti-Rh autoantibodies.[49] It thus seems likely that escape of some autoreactive $CD4^+$ T cells may be involved in generation of AIHA. However, it has also been reported that γ/δ T cells, which are not specific for RBC antigens, can provide help to anti-RBC autoreactive B cells.[50] Thus, it is also possible that T cells of other specificities can give bystander help to anti-RBC B cells. In addition, T cells specific for cryptic epitopes may also be involved. Thus, it appears that although T cells are likely involved in helping autoreactive B cells differentiate into plasma cells, the exact nature of such help may vary.

The activation of autoreactive B cells specific for RBC antigens is an absolute requirement for the generation of AIHA. Like thymic education of T cells, education of autoreactive B cells requires that immature B cells encounter the self-antigen, which results in either deletion or the induction of anergy.[51] Although deletion of autoreactive B cells can occur in the periphery,[52] B cells that encounter the antigen, recognized by their rearranged immunoglobulin gene, while still in the bone marrow undergo arrested development and death.[53] In addition, B cells are more easily tolerized to membrane-bound surface antigens than to soluble antigens.[52] Because erythroid development occurs in the bone marrow where immature B cells appear to first undergo education, and because blood group antigens are membrane-bound proteins, it seems likely that deletion of autoreactive B cells that recognize RBC antigens is a highly efficient process. Nonetheless, it has been demonstrated that while autoreactive B cells specific for RBC antigens are mostly deleted or rendered anergic, there is sufficient survival of autoreactive B cells to cause AIHA in some settings.[54,55] The autoreactive B cells that survive in this setting appear to reside predominantly in gut tissues, and their activation can be significantly influenced by the presence of enteric pathogens or inflammation.[55]

If autoreactive cells manage to escape central tolerance, they can still be deleted or inhibited via peripheral tolerance, a second process that prevents autoreactive cells from differentiating into mature effector cells that may cause autoimmunity. The distinction between central and peripheral tolerance, which is clear for T cells (thymic versus extrathymic), is less well defined for B cells. Mechanisms of peripheral tolerance include induction of apoptosis, anergy, and active inhibition by suppressor/regulatory T cells. This combination of central tolerance, which eliminates most autoreactive cells, and peripheral tolerance, which inhibits those few autoreactive cells that escape, is generally effective; AIHA is a relatively rare event. However, the presence of autoreactive lymphocytes essentially constitutes a pre-existing risk factor for AIHA if the normal factors that keep autoreactive lymphocytes at bay are sufficiently perturbed.

Several events can lead to the inappropriate activation of peripheral autoreactive cells. Infection with a pathogen that carries epitopes similar to blood group antigens *(molecular mimicry)* can provide sufficient stimulation of autoreactive cells in an inflammatory environment such that peripheral tolerance is overcome. Alternatively, general immune dysregulation and polyclonal activation of lymphocytes may nonspecifically activate T and/or B cells that happen to be specific for RBC antigens. In support of this concept, development of AIHA is associated with chronic inflammation and lymphoproliferative disorders in both human and animal models[56,57] and is also associated with a variety of infections, including *Mycoplasma pneumoniae*, Epstein-Barr virus, cytomegalovirus, and rubella.[58] Cytokine dysregulation may also play a role, as a polarization to a Th2-type profile in AIHA has been observed in both humans and in the NZB/W murine model of AIHA.[59,60] Additional mechanisms include a loss of regulatory T cells, as CD4+ CD25+ T reg levels appear to be decreased in AIHA.[61] Thus, the breakdown of peripheral tolerance by a variety of mechanisms may allow the few autoreactive lymphocytes that escape central tolerance to differentiate into mature effectors that ultimately result in the formation of plasma cells that secrete antibodies specific for blood group antigens.

An additional mechanism of loss of tolerance involves the generation of cryptic peptide epitopes. For any given protein, only a limited number of peptides are normally presented by MHC molecules. The repertoire of peptides presented by each individual is largely a function of their HLA type, because peptides differ in their affinities for the grooves of different MHC variants. The range of peptides presented is also a function of how a protein is processed and broken down by a system of protease complexes called the *proteosome*. It has been demonstrated that a given protein may contain peptide sequences that fit well into an MHC molecule but are not typically presented on MHC because that particular peptide fragment is not generated by proteolysis of the protein in question. Such a peptide is called a *cryptic epitope*.

Because cryptic epitopes will not be processed and presented by normal thymic tissues, T cells that recognize cryptic epitopes will not be deleted in the thymus. Such T cells are technically not autoreactive, because the cryptic epitopes are also not presented on peripheral tissues and thus do not constitute a self-antigen. However, abnormal processing of self-proteins can result in presentation of cryptic epitopes on self-tissues. For example, ongoing inflammation and microbial infection leads to the release of microbial proteases and a large-scale breakdown of self-proteins by inflammatory proteases released from leukocytes. Infection of APCs by microbes may also change the processing of self-antigens. Furthermore, cryptic epitopes may be generated by exposure to caustic stimuli that denature or destroy proteins, such as burns or chemicals. The generation of such peptides may lead to activation of T cells specific for the cryptic epitope, which would then be capable of providing T-cell help to a B cell presenting the same cryptic epitope. Once a B cell has differentiated into an antibody-secreting plasma cell, it no longer requires immune stimulation to produce antibodies. Thus, in theory, a sustained autoantibody response can be generated during a transient exposure to cryptic epitopes. Direct experimental evidence demonstrates that cryptic epitopes of Rh antigens are recognized by T cells in patients with AIHA of anti-Rh specificity.[62–65]

Transfusion-Associated AIHA

A considerable percentage of AIHA patients develop an anti-RBC autoantibody subsequent to transfusion with allogeneic RBCs. Several studies have examined the association between transfusion and the development of anti-RBC autoantibodies. The phenomenon has been observed with considerable

frequency in patients with sickle cell anemia. For example, one study reported that 8% of pediatric patients and 9.7% of adults with sickle cell anemia who received transfusions developed anti-RBC autoantibodies. In a separate retrospective study, of 2618 patients with a positive DAT or indirect antiglobulin test, 121 (4.6%) were reported to also have autoantibodies. Of the patients with autoantibodies, 10% also had an identifiable alloantibody and generated both the alloantibody and autoantibody subsequent to transfusion.[66] Due to the inability to obtain transfusion records on all patients, this frequency of autoimmunization secondary to transfusion may be an underestimate.

Although the generation of new anti-RBC autoantibodies can have a strong temporal association to antecedent RBC transfusion, such observations constitute only a correlation and do not establish causality. Moreover, as transfusion recipients clearly have an underlying pathology that necessitates the transfusion in the first place, it is practically impossible to isolate the transfusion as the only variable. However, several settings do allow independent investigation of the role of transfusions on autoantibody development. For example, normal Rh-negative volunteers can be transfused with Rh-positive blood to generate a source of anti-Rh immunoglobulin.[17] In one study involving 34 volunteers, two participants developed a positive DAT on their own RBCs during the immunization protocol.[17] No clinical hemolysis was observed in these two individuals, but RBC survival studies that could detect low-level hemolysis were not carried out. Additionally, in an animal model of transfusion-induced AIHA, repeated transfusion of xenogeneic RBCs (rat into mouse) results in the generation of autoantibodies.[67] Taken together, these observations indicate that generation of autoantibodies can be a direct sequelae of transfusion of RBCs.

Mechanisms of Autoimmunization by Transfusion

The mechanisms by which allogeneic RBC transfusion induces an anti-RBC autoantibody are undetermined. However, as with the development of spontaneous autoantibodies, it is likely that several mechanisms are involved. First, any of the aforementioned immunologic perturbations involving loss of tolerance, which may contribute to the spontaneous generation of AIHA, may also contribute to transfusion-associated AIHA. However, in addition to the general breakdown of immune tolerance, several mechanisms unique to transfusion-induced AIHA require special mention here.

Linked Recognition of Foreign T-Cell Epitopes and Self B-Cell Epitopes

One detriment of the human immune system's use of linked recognition of T-cell and B-cell epitopes is that slightly altered self-antigens run a considerable risk for inducing humoral autoimmunity. For example, there are cases in which, although thymic education is complete, some B cells with immunoglobulins that recognize self-antigens persist. This appears to be the case for B cells specific for RBC antigens.[54,55] When these autoreactive B cells encounter the antigen recognized by their rearranged immunoglobulins, the antigen is phagocytosed and peptides from that antigen are presented on class II MHC molecules of the B cell. In this scenario, because all T cells that are capable of recognizing such peptide–MHC complexes have been deleted in the thymus, humoral tolerance is maintained. However, this mechanism of tolerance fails if the self-protein recognized by an autoreactive B cell has a foreign T-cell epitope attached to it. In this setting, the B cell now presents a foreign peptide–class II MHC epitope and receives the help required to differentiate into an antibody-secreting plasma cell. Thus, the linkage of a foreign T-cell epitope to a self B-cell epitope may result in humoral autoimmunity.

For such a mechanism to have physiologic relevance, one must ask in what situations would the immune system encounter a self B-cell epitope linked to a foreign T-cell epitope. One scenario is the exposure to foreign human tissues during transfusion. Many genes have numerous allelic variants throughout the human population. This is perhaps best demonstrated in the extensive catalog of human blood group antigens that have now been described. Although the described allelic variations of blood group antigens have been predominantly detected serologically, and are thus best known as B-cell epitopes, they can also serve as T-cell epitopes if the HLA of a given individual can present peptides containing the amino acid variation. Moreover, there may be a considerable number of polymorphisms that do not alter B-cell epitopes and have thus not been detected serologically, but can still constitute a variant of a T-cell epitope presented by class II MHC molecules. For example, a donor and recipient may both be positive for the Rh D epitope. However, the donor may have an amino acid difference in an internal portion of the Rh molecule. If the peptide containing this variation can be presented by the recipient HLA, then this constitutes the linkage of a foreign T-cell epitope to a self B-cell epitope. This is precisely the situation in which T-cell tolerance would be circumvented. This mechanism is hypothetical in the context of RBC transfusion and has not been formally tested. However, it is consistent with well-established experimental immunology in which linkage of foreign T-cell epitopes to self B-cell epitopes can lead to autoantibodies.[68]

"Autoantibodies" of Donor Origin: RBC-Specific Humoral Graft-versus-Host Disease

When an individual's immune system generates antibodies against their own tissue, it is generally assumed that their own B cells are the origin of the antibody. However, transfusion of blood results in the introduction of foreign B cells into the recipient. Because transfused leukocytes have the capacity to proliferate, transfusion of very few cells can be sufficient to generate a chimeric state. Indeed, it has been reported that even in the case of leukoreduced blood, sufficient leukocytes are transfused to cause microchimerism in some patients.[69] Thus, transfusion of RBCs introduces donor lymphocytes into the recipient immune system.

Aside from special populations at risk for transfusion-associated graft-versus-host disease (GVHD), including immunosuppressed patients and related individuals, the clinical consequences of transfusing foreign leukocytes are seldom significant. Transfusion of nonleukoreduced blood is routinely performed without any observable negative consequences. However, there are exceptions. It has been reported that in one patient transfusion-associated anti-RBC "autoantibodies" had immunoglobulin allotypes that were not part of the patient's genome.[70] Although one cannot rule out the possibility of spontaneous mutation of a patient's allotypes, the most likely explanation is that the antibodies were produced by B cells from a transfusion donor. A certain number of transfusion-associated anti-RBC autoantibodies

may therefore not actually be "autoantibodies," but instead may be alloantibodies synthesized in situ by donor B cells, thus actually representing humoral GVHD.

Typically, transfused leukocytes are rejected by the recipient immune system as foreign. It is thus unclear why a transfused B cell would survive and differentiate into a plasma cell. In addition, it seems very unlikely that alloreactive B cells would be transfused, because the precursor frequency of donor B cells specific for recipient RBC antigens is expected to be low and relatively few B cells are transfused even in nonleukoreduced blood. However, it has been pointed out that up to 10% of transfusion donors were previously transfusion recipients.[71] In addition, any female who has carried a child may be alloimmunized to paternal RBC antigens. Given these facts, donor precursor frequencies of anti-RBC B cells may be higher than expected. Because these RBC-specific B cells would likely be memory cells, their activation requirements would be lower, which may make engraftment and antibody production more likely. The frequency by which this phenomenon occurs is undetermined.

CELLULAR IMMUNIZATION IN RESPONSE TO RBC TRANSFUSION

Typically and traditionally, clinical monitoring of immunization to RBCs is carried out by screening for antibodies that are detected by an agglutination reaction. This process of mounting an antibody response to transfused RBCs is known to involve activation and differentiation of $CD4^+$ helper T cells that recognize peptides from RBC antigens presented on class II MHC molecules of the recipient's APCs. The activated helper T cells then give the required signals to antigen-specific B cells to allow differentiation into antibody-secreting plasma cells.

However, in addition to helper T cells, it has also been appreciated that transfusion of blood products can result in the generation of class I MHC-restricted $CD8^+$ T cells with lytic activity. Except in exceptionally rare cases of autoimmunity, cellular immunity is not known to be capable of contributing to hemolysis of transfused RBCs.[72] Nonetheless, to the extent that multiply transfused patients ultimately receive bone marrow or organ transplants, the generation of cellular immunity is relevant in that it can contribute to subsequent transplant rejection.

Traditionally, units of packed RBCs have not been stringently leukoreduced. This results in the transfusion of a small but significant number of leukocytes of donor origin. Because leukocytes express class I MHC and can also serve as APCs, direct alloimmunization to donor MHC molecules results in activation of recipient T cells specific for donor human leukocyte antigens (HLAs). This can contribute to rejection of donor organs and bone marrow if they share the same HLA.

The widespread implementation of leukoreduction filters for units of RBCs has significantly limited the exposure of transfusion recipients to donor leukocytes. Because human RBCs do not express MHC (with the possible exception of the Bg blood group), direct alloimmunization of recipient T cells is highly unlikely. However, it has been reported that minor histocompatibility antigens on donor RBCs are efficiently crosspresented into the class I MHC of recipient APCs.[30] This results in expansion of recipient $CD8^+$ T cells specific for the minor histocompatibility antigen. In the context of transplantation of HLA-matched tissues, this immunization to minor histocompatibility antigens may contribute to rejection if the organ donor and transfusion donor have the same minor histocompatibility antigens. Thus, although leukoreduction of blood products may significantly decrease rates of alloimmunization to major histocompatibility antigens, transfusion of RBCs themselves has the potential to immunize against minor histocompatibility antigens. As previously discussed, this has little relevance to transfusion, because cellular responses do not typically lyse RBCs. However, it is relevant in the setting of the patient receiving transfusions as support prior to transplantation.

BASIC SCIENCE OF RBC DESTRUCTION

Nonimmunologic Mechanisms of Hemolysis

Hemolysis of transfused RBCs is the major sequelae prevented by crossmatching blood prior to transfusion. Despite this precaution, occasionally one observes the hemolysis of crossmatch-compatible blood. In some cases, hemolysis of crossmatch-compatible blood is an immune-mediated mechanism that involves undetected antibodies. However, mechanisms exist by which transfused RBCs can be hemolyzed in the absence of an alloantibody.

To begin with, nonimmune-based physical factors can lead to hemolysis. For example, erythrocytes are highly sensitive to osmotic damage. Thus, if RBCs are transfused through an intravenous line that is simultaneously delivering hypotonic saline, direct lysis can occur. This can lead to massive hemolysis that presents clinically as an acute hemolytic transfusion reaction. Alternatively, RBC hemolysis can occur in the recipient due to nonantibody-based factors. For example, it has been reported that transfusion of RBCs from donors deficient in glucose-6-phosphate dehydrogenase can result in considerable hemolysis, especially in infants.[73–76]

There are also antibody-dependent mechanisms of RBC destruction that do not require antibody binding to the RBCs. For example, large-scale complement activation by immune complexes not associated with RBCs can lead to complement sensitization of nearby RBCs that leads to "bystander hemolysis" of RBCs not coated with antibodies.[77] In addition, cellular immunity can lead to hemolysis in rare settings, and it has been reported that natural killer cells can lyse RBCs in DAT-negative AIHA.[72]

Despite these nonimmunologic mechanisms of RBC destruction, one must take care not to mistakenly exclude antibody-mediated hemolysis on the basis of a negative antibody screen. Although an anti-RBC antibody is usually detectable with immune-mediated destruction of transfused RBCs, there are exceptions. It has been observed that Rh-positive RBCs have a decreased life span in Rh-negative individuals previously exposed to Rh-positive blood, even if no anti-Rh is detectable.[78] Such individuals typically proceed to generate detectable anti-Rh antibodies on subsequent transfusion with Rh-positive blood. Thus, there appears to be a level of anti-RBC antibody that is capable of causing hemolysis but is below the threshold of detection by agglutination-based assays. In addition, not all antibodies that bind RBCs in vivo are detected in vitro. Also, anamnestic responses

may result in an initial negative screen followed by a delayed hemolysis and conversion to a positive screen.

Antibody-Mediated Hemolysis

Although certain antibodies, such as anti-A and anti-B IgM, cause rapid intravascular hemolysis through complement fixation, the majority of clinically significant anti-RBC antibodies lead to delayed hemolytic transfusion reactions, in which hemolysis occurs over a matter of days to weeks. In this process, RBCs are opsonized by IgG, which can be augmented by complement proteins and results in removal of the RBCs by cells of the reticuloendothelial system. This occurs in the extravascular space and is mediated predominantly by tissue macrophages in the spleen and liver. In addition to hemolysis as a result of RBC phagocytosis, RBCs can also be lysed by the direct release of lysosomal proteases.[77] However, in either case, the process is facilitated by anti-RBC immunoglobulin.

There has been considerable investigation into the isotype and subclass of antibodies involved in hemolysis of RBCs. The majority of this work has been performed in the setting of AIHA, but likely applies to hemolysis of incompatible transfusions as well. The predominant antibody involved in delayed hemolytic transfusion reaction is of the IgG type. The presence of IgG on the RBC surface effectively opsonizes the RBC through interaction with Fc receptors on phagocytic macrophages predominantly in the spleen and liver. Although anti-RBC IgM typically results in complement-mediated intravascular hemolysis, IgM has been reported to promote a delayed hemolytic reaction in some settings.[77] This likely occurs through deposition of complement proteins on the RBC surface, which opsonizes RBCs via complement receptors on macrophages, because macrophages do not express IgM-binding Fc receptors. In support of this notion, it has been reported that IgM-coated RBCs have a normal life span in humans with complement deficiencies.[77] Although very uncommon, isolated anti-RBC IgA molecules have also been reported in patients with hemolysis.[77] However, the conclusion that the IgA is responsible for hemolysis in this setting is predicated on the assumption that no IgG was present. As it has been shown that the level of IgG necessary to induce hemolysis can be below the level of detection by standard anti-RBC IgG assays, the legitimacy of this assumption is unclear.

The potential of different IgG subclasses to induce hemolysis has been studied in both humans and mice. Several groups have performed large-scale analysis of DAT-positive patients with or without clinically evident AIHA in an attempt to identify the IgG subclass dependence of hemolysis.[79–82] Garratty performed an in-depth comparison of IgG subclasses involved in DAT-positive individuals with or without AIHA.[82] This analysis of 78 patients showed IgG1 to be the sole IgG subclass present in the majority of AIHA cases. However, IgG1 was also found on 72% of patients without clinical AIHA, and the presence of IgG1 does not predict whether a DAT-positive individual will experience hemolysis. In an analysis of 304 patients, Sokol and colleagues reported similar findings, with anti-RBC IgG1 present in 98% of cases and IgG1 as the sole subclass in 64% of cases.[80] A smaller analysis of 34 patients also had similar findings concerning the predominance of IgG1.[80] Garratty's analysis also demonstrated that some patients had IgG2 alone or IgG3 alone, but that neither was more prevalent in patients with AIHA compared with patients with no hemolysis. Isolated IgG4 was found only in five normal blood donors and none of the AIHA patients analyzed.

The above findings demonstrate that although IgG1 is the most common anti-RBC IgG subclass, isolated IgG1, IgG2, and IgG3 can lead to hemolysis. However, the detection of an isolated IgG subclass does not predict the likelihood of hemolysis. In contrast, the presence of multiple simultaneous subclasses clearly shows an increased risk for hemolysis.[82] Although this could represent a cooperativity of subclass, the presence of multiple IgG subclasses resulted in a larger amount of overall IgG on the RBC surface.[80] Indeed, it has been reported that the overall quantity of IgG on the RBC surface predicts the likelihood of hemolysis in vivo.[77,79,80,83–87]

Considerable evidence exists suggesting that additional genetic and environmental factors may play a role in the question of IgG subclass and hemolysis. For instance, in contrast to the above conclusions, it has been reported that IgG3 is more potent than other subclasses at promoting RBC phagocytosis by monocytes,[88] and it has also been reported that AIHA with IgG3 involvement may be less responsive to treatment.[89] However, a direct comparison in the clearance of Rh-positive cells from Rh-negative volunteers given monoclonal anti-Rh of the IgG1 or IgG3 type showed that RBCs were cleared from IgG1 recipients at a significantly higher rate than in IgG3 recipients.[90] Interestingly, volunteers receiving IgG3 had a wide distribution of responses, with rapid clearance in some individuals and slow clearance in others. Subsequent studies by Kumpel and colleagues demonstrated that naturally occurring allelic variants in the FcγRIIIa receptor alter the efficiency with which IgG3-coated RBCs are cleared.[91] In addition, an animal model of IgG-induced hemolytic anemia demonstrated that concurrent viral infection significantly enhances disease with a hemolytic IgG2a antibody but not with a hemolytic IgG1 antibody due to an increase in erythrophagocytic capacity of macrophages.[92] Thus, genetic variation in accessory molecules other than IgG may alter the IgG subclass dependence of AIHA in different patient populations. Likewise, environmental factors and patient-specific pathology that leads to inflammation and macrophage activation may significantly affect hemolysis by RBC-binding antibodies.

Although animal models are biologically distinct from human physiology, they represent a setting in which highly controlled studies can be carried out on genetically identical subjects in a controlled environment. Izui and colleagues and others have made extensive use of a murine model of AIHA to dissect out the biology of IgG-mediated RBC hemolysis.[92–98] In this model system, both high-affinity and low-affinity monoclonal antibodies against the RBC autoantigen have been isolated. Similar to human IgG-mediated hemolysis, complement does not appear to be required for RBC removal in the murine model, because hemolytic anemia still occurs in mice lacking C5 or C3.[93] However, both Fc receptor-dependent phagocytosis (mostly in the liver) and RBC sequestration of RBCs (mostly in the spleen) contribute to decreased hematocrit in response to autoantibodies.[93]

To control for intrinsic differences in the epitope specificity and affinity of different monoclonal antibodies, recombinant genetics have been employed to create artificial monoclonal antibodies of each murine IgG subclass that have precisely the same epitope-binding domains. IgG1, IgG2a, and IgG2b were each hemolytic, whereas IgG3 did not promote significant hemolysis.[96] IgG2a was 20 to 100 times more potent in inducing hemolysis than IgG1 or IgG2b. Gene deletion

studies demonstrated that the FcγRIII receptor was responsible for hemolysis by IgG1, whereas both FcγRI and FcγRIII were involved in hemolysis by IgG2a and IgG2b. FcγRIIB did not appear to contribute to hemolysis, consistent with its generally understood role as an inhibitory molecule. Recently, a new FcγR has been identified (FcγRIV), which binds both IgG2a and IgG2b and can contribute to antibody-mediated thrombocytopenia.[99] The role of FcγRIV has not yet been formally tested in antibody-mediated hemolysis.

Antibody-Induced Antigen Loss/Suppression

Although many anti-RBC antibodies can result in either intravascular or extravascular hemolysis of the RBCs that they bind, hemolysis is not the inevitable result of antibody binding. There are certainly a considerable number of individuals who have strongly positive DATs without hemolysis. Moreover, numerous antibodies have been described against "clinically insignificant" blood group antigens for which crossmatch-incompatible blood can be transfused without ill effect. Additionally, there is a somewhat obscure (but well described) phenomenon in which the RBC phenotype will convert from positive to negative for a given antigen after encountering immunoglobulins that bind to the antigen. This phenomenon has been referred to as weakened antigenicity, antigen reduction, antigen suppression, or acquired loss and has been reported to occur for many blood group antigens, including Rh (D and e), Kell, Kidd, Duffy, Lutheran, LW, Co, Ge, En(a), AnWj, and Sc1.[77,100–112]

Although the mechanisms of antigen loss have not been fully elucidated, publications documenting the phenomenon have proposed a number of possible explanations. It has been suggested that the antibodies to a given RBC antigen are toxic to newly formed RBCs and that the presence of such antibodies alters hematopoiesis such that only antigen-negative RBCs escape the marrow intact.[102,105] However, this proposed mechanism cannot account for the observation that antigen loss can also be seen in the setting of transfusion of crossmatch-incompatible RBCs, which have already synthesized the antigen being recognized.[101,107] It has also been suggested that antigens might be lost due to factors other than immunoglobulins, such as destruction by microbial enzymes. However, suppression of antigen correlates more with the presence of antibody and, in most cases, antigen suppression does not involve a documented infection. Nonetheless, the presence of subclinical infections cannot be ruled out. It has also been suggested that antibody binding results in the shedding of antigen from mature erythrocytes through formation of antigen–antibody immune complexes.[102]

Insights into the mechanisms of antibody-induced antigen loss have been gained from an animal model of this phenomenon. It has been reported that presynthesized antigen is shed from transfused RBCs while leaving the RBC intact and without decreasing circulatory life span.[113] This process requires the presence of both IgG and FcγRIII, but it occurs normally in splenectomized animals. Thus, in this animal model, antigen loss involves neither bone marrow suppression of RBC antigen synthesis nor microbial destruction. In contrast, antigen appears to be lost through interactions between RBCs coated with IgG and FcγRIII-bearing cells. However, the exact mechanism in humans remains to be determined, and antigen loss may occur as a result of distinct mechanisms in different settings.

It is unclear why mechanisms that result in antibody-induced antigen loss may evolve. In this context, it is worth noting that biological mechanisms have been described by which RBCs shed whole antigens as part of normal RBC biology. CD35, which is also known as the CR1 complement receptor and the Knops blood group antigen, is a receptor for the C3b fragment of complement.[114] In what has been termed the *immune-adherence phenomenon,* circulating immune complexes or antibody-bound bacteria bind to RBCs via interactions of CD35 on RBC and C3b on the immune complex.[115,116] When a RBC encounters hepatic macrophages, the immune complex is transferred to the phagocyte. Like antibody-induced antigen loss, RBCs delivering immune complexes to macrophages lose their CD35 surface antigen but are not destroyed.[117–119] Because this process appears to depend on the Fc portion of the antibodies, interactions with Fc receptors may also be involved.[120] Furthermore, because immune complex transfer occurs in the liver,[120,121] an intact spleen is presumably not required. Whether loss of CD35 is due to complete removal of the molecule or due to proteolytic fragmentation by Fc-bearing cells is unresolved. However, it has been demonstrated that no residual cytoplasmic domain of CD35 remains after loss of CD35 from podocytes during immune complex–based pathophysiology of lupus, a situation that resembles CD35 loss from RBC delivering immune complexes to phagocytes.[122] Thus, despite the fact that CD35 is a transmembrane protein, complete extrusion of the CD35 molecule seems a distinct possibility. Overall, the natural process of RBC-mediated delivery of immune complexes to the liver resembles antibody-mediated antigen loss in several regards and suggests that antibody-induced antigen loss may be functioning through existing pathways that evolved to deliver immune complexes to hepatic macrophages.

ii. Red Blood Cell, Platelet, and Leukocyte Antigens and Antibodies

Chapter 5

Membrane Blood Group Antigens and Antibodies

Marion E. Reid • Connie M. Westhoff

Erythrocyte blood group antigens are polymorphic, inherited carbohydrate or protein structures located on the outside surface of the red blood cell (RBC) membrane. Our ability to detect and identify blood group antigens and antibodies has contributed significantly to the current safe, supportive blood transfusion practice and to the appropriate management of pregnancies at risk for hemolytic disease of the fetus and newborn (HDN). Exposure to erythrocytes carrying an antigen lacking on the RBCs of the recipient can elicit an immune response in some individuals. Thus, blood group antigens are clinically important in allogeneic blood transfusions, maternofetal blood group incompatibility, and organ transplantation.

By virtue of their relative ease of detection and generally straightforward mode of inheritance, blood group antigens have been used in genetic, forensic, and anthropologic investigations. The polymorphisms of blood groups have been exploited as a tool to monitor in vivo survival of transfused RBCs, to monitor engraftment of bone marrow transplants, and to monitor for blood doping by allogeneic transfusion in sports and athletics. Antigen profiles have been used to predict inheritance of diseases encoded by a gene in close proximity to the gene encoding the blood group antigen (e.g., the association of gene deletions causing chronic granulomatous disease with the loss of expression of Kell). Blood group antigens have also contributed to our understanding of cell membrane structure. The lack of Kell/Kx expression is associated with acanthocytes, Rh-deficient RBCs are stomatocytic, and mild elliptocytosis occurs in RBCs lacking Gerbich glycophorin C (GPC) and/or glycophorin D (GPD).

More recently, in the postgenomic era, knowledge about the molecular basis associated with blood group antigens and phenotypes is being applied to the detection of single nucleotide polymorphisms (SNPs) associated with blood group antigens. Microarray and microchip technologies hold promise for transfusion medicine testing.

This chapter reviews the scientific basis of molecules that express RBC blood group antigens and their relevance and application to the practice of transfusion medicine. One of the most important clinical concerns in contemporary transfusion medicine occurs with the discovery that a patient requiring transfusion has an unexpected blood group antibody. Although the laboratory can characterize an antibody in terms of specificity, immunoglobulin class, and in vitro characteristics, it cannot always predict the antibody's clinical significance. Therefore, when a blood group antibody is detected, an important, although often overlooked, first step is to review all available pertinent patient information (Table 5–1). One can then assess the potential for adverse effects by correlating the serologic information with the patient history and also with historical clinical experience in other patients. A patient who has not been exposed to RBCs by transfusion or pregnancy is unlikely to have a clinically significant alloantibody.

ERYTHROCYTE MEMBRANE

The erythrocyte membrane consists of lipids, proteins, and carbohydrates, which interact to form a dynamic and fluid structure. By dry weight, the ratio of protein-to-lipid-to-carbohydrate in the RBC membrane is 49:43:8. The RBC membrane behaves as a semisolid, with elastic and viscous properties that are not observed with simple lipid vesicles. These properties are critical for the RBC to survive in the circulation for approximately 120 days during numerous cycles (approximately 75,000) and passages through narrow veins and sinusoids in the spleen. The RBC accomplishes this goal without intracellular machinery to repair damage. The multiple connections between the membrane skeleton and the lipid bilayer cause the bilayer to follow the contours of the membrane skeleton. Together, the membrane skeleton and lipid bilayer give the erythrocyte shape and resilience.[1,2]

Lipids

The lipids in the RBC membrane form a bilayer, with the hydrophobic tails on the inside and the hydrophilic polar head groups to either the outside (extracellular) or the inside (cytoplasmic) surface (Fig. 5–1). The following three types of lipids occur in the RBC membrane: phospholipid (50%), cholesterol (40%), and glycolipids (10%). The arrangement

Table 5–1 **Information for Problem-Solving in Immunohematology**

Available Information	Considerations
Patient demographics	Diagnosis, age, sex, ethnicity, transfusion and/or pregnancy history, drugs, intravenous fluids (lactated Ringer's solution, IVIgG, antilymphocyte globulin), infections, malignancies, hemoglobinopathies, stem cell transplantation
Initial serologic results	ABO, Rh, direct antiglobulin test, phenotype, antibody detection, autologous control, crossmatch
Hematology/chemistry values	Hemoglobin, hematocrit, bilirubin, lactate dehydrogenase, reticulocyte count, haptoglobin, hemoglobinuria, albumin:globulin ratio, red blood cell (RBC) morphology
Sample characteristics	Site and technique of collection, age of sample, anticoagulant, hemolysis, lipemic, color of serum/plasma, agglutinates/aggregates in the sample
Other	Check records in current and previous institutions for antibodies to blood group antigens
Antibody identification	Autologous control, phase of reactivity, potentiator (saline, albumin, low-ionic-strength solution, polyethylene glycol), reaction strength, effect of chemicals on antigen (proteases, thiol reagents), pattern of reactivity (single antibody or mixture of antibodies), characteristics of reactivity (mixed field, rouleaux), hemolysis, preservatives/antibiotics in reagents, use of washed RBCs

of phospholipids in the bilayer is asymmetrical. The outer leaflet predominantly contains the neutral phospholipids (phosphatidylcholine and sphingomyelin), and the inner leaflet predominantly contains the aminophospholipids (phosphatidylethanolamine and phosphatidylserine). The presence of phosphatidylserine, which is negatively charged, on the inner monolayer results in a significant difference in charge between the two sides of the bilayer. The lipid molecules can diffuse rapidly within their own monolayer, but they rarely "flip-flop," maintaining membrane "sidedness."[1]

Proteins

Peripheral proteins form a meshwork under the lipid bilayer that is called the *membrane skeleton*. This name implies a relatively rigid structure; however, the meshwork is actually fluid and flexible. The RBC membrane skeleton is associated with the lipid bilayer through specific interactions with transmembrane proteins.

Specific protein components of the RBC membrane skeleton, which is associated with the inner leaflet of the lipid bilayer, interact with the cytoplasmic domains of some antigen-carrying transmembrane proteins.[3–5] Two major and well-defined interactions are ankyrin, which binds to spectrin in the membrane skeleton and the cytoplasmic domain of the multipass transmembrane protein, band 3 (anion exchanger, AE1),[6–14] and protein 4.1, which provides a link between spectrin, actin, and p55 in the membrane skeleton to the single-pass transmembrane proteins GPC and GPD.[15–22] Some integral transmembrane proteins interact with other transmembrane proteins, forming either small or large macromolecular complexes (e.g., glycophorin A (GPA) with glycophorin B (GPB)[2]; band 3 with GPA[23–27]; Kell with Kx[28,29]; RhD, RhCE, RhAG,

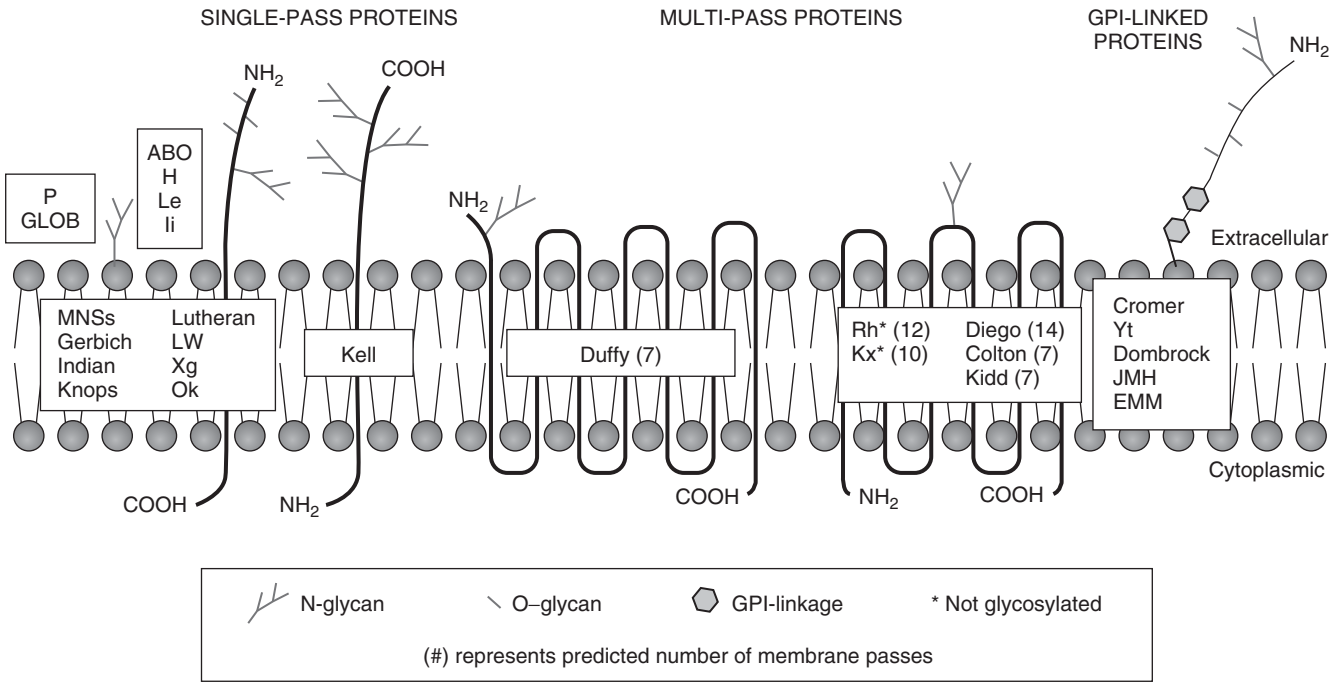

Figure 5–1 Diagram of a cross-section of the red blood cell membrane lipid bilayer and various membrane components that carry blood group antigens. GPI, glycosylphosphatidylinositol.

LW (ICAM4), CD47, and GPB).[4,30] The recent discovery that the Rh–RhAG complex interacts with cytoskeletal ankyrin[31] suggests that there are additional attachment sites between integral membrane proteins and the membrane skeleton and provides an possible explanation for the stomatocytosis associated with Rh-null erythrocytes.

Many blood group antigens are carried on transmembrane proteins or glycoproteins; however, a few antigens are carried on glycosylphosphatidylinositol (GPI)-linked proteins (see Fig. 5–1). Antigens in two blood group systems (Lewis and Chido-Rodgers) are carried on proteins that are adsorbed onto RBCs from the plasma.

Carbohydrates

Carbohydrates are essentially restricted to the extracellular surface of the RBC membrane, where they collectively form a negatively charged environment that is largely responsible for keeping the RBCs from adhering to one another and to the endothelium. The majority of carbohydrates are attached to lipids on ceramide and to proteins by attachment to asparagine (N-linked) or to serine or threonine (O-linked) during passage through the lumen of the Golgi.[32] Some blood group antigens are determined by the terminal carbohydrate residue (e.g., A and B) whereas others require the presence of a chain of carbohydrate residues (e.g., Le^b and I).

The carbohydrates form the *glycocalyx,* a negatively charged barrier approximately 10 Å thick around the outside of the RBC membrane. This barrier can keep immunoglobulin G (IgG) antibodies, particularly those recognizing antigens that reside close to the lipid bilayer, from readily interacting with the corresponding antigen. Thus, the glycocalyx affects the ability of an IgG antibody to cause direct agglutination.

RBC BLOOD GROUP ANTIGENS

Figure 5–1 depicts the membrane components that are known to carry blood group antigens. Some antigens are carbohydrates attached to lipids or to proteins, some are protein, and some require both protein and carbohydrates. Although the blood group antigens do not themselves have a function, the molecules on which they are carried do. The function of proteins carrying blood group antigens has been determined through observation of the morphology of RBCs that lack the protein (Table 5–2), direct experimentation, or comparison of the predicted protein sequence with protein databases to identify similar proteins whose function is known, even if in other tissues or organisms.

Recognition of a blood group antigen begins with discovery of an antibody. When an individual whose RBCs lack an antigen is exposed to RBCs that possess that antigen, the person may mount an immune response and produce an antibody that reacts with the antigen. Depending on the immunoglobulin class of the antibody and, to some extent, on the number and topology of antigens on the RBC membrane, the interaction between antibody and antigen may be detected by agglutination or hemolysis or may require an antiglobulin reagent. In human blood grouping, most tests involve agglutination, in which clumping of the RBCs serves as the detectable end point.[33] The polymorphic erythrocyte marker is given a blood group antigen name after genetic and family studies.

Terminology

A working party on terminology for RBC surface antigens, sanctioned by the International Society for Blood Transfusion (ISBT), has categorized the blood group antigens into four classifications[34]: the genetically discrete blood group systems (Table 5–3 summarizes the name, ISBT system number, chromosome location, gene name, associated antigens, component name, and possible functions for each system); blood group collections that consist of serologically, biochemically, or genetically related antigens; 700 series of low-incidence antigens; and 901 series of high-incidence antigens (Table 5–4 contains the ISBT name, number, and associated antigens. The chromosome location for these antigens has not yet been determined).

As RBC antigens were discovered, notations were devised to describe them. The terminology used is inconsistent: a single letter (e.g., A, D, K), a symbol with a superscript (e.g., Fy^a, Jk^b, Lu^a), or a numerical notation (e.g., Fy3, Lu4, K12) is used. Even within the same blood group system, antigens have been named with different schemes, resulting in a cumbersome terminology for describing phenotypes. The use of the same symbol with a different superscript letter (e.g., Fy^a and Fy^b) indicates products of alleles (antithetical antigens).[34] Some confusing terminology persists; for example, the P1 antigen is the sole antigen in the P blood group system, and the P antigen is the only antigen in the GLOB system. There is also a GLOB collection, with Pk and LKE antigens. In clinical practice, the traditional terminology is still extensively used; this is the terminology that will be used throughout this chapter for the discussion of red cell antigens.

Collectively, there are over 260 antigens recognized by the ISBT. We restrict discussion to the more commonly encountered antibodies and antigens.

Inheritance

Most blood group antigens are encoded by genes on autosomes.[35] Most are codominant (e.g., M/N, E/e, K/k, Fy^a/Fy^b),

Table 5–2 **Red Blood Cell Morphology and Associated Phenotype**

Shape	Clinical Manifestation	Protein	Phenotype
Stomatocyte	Mild hemolytic anemia	Absent Rh or RhAG (Rh50)	Rh-null, Rh-mod
Elliptocyte	Slightly reduced red blood cell survival	Absent GPC and GPD	Ge2, Ge3, Ge4 (Leach)
Acanthocyte	Elevated creatinine phosphokinase, muscular choreiform movements, neurologic defects, reduced RBC survival	Absent Kx	McLeod

Table 5–3 Genetically Discrete Blood Group Systems

Name	ISBT Number	Chromosome Location	Gene Name ISBT	Gene Name ISGN	Associated Antigens	Component Name	Possible Function

Series		
Low-incidence antigens	700	By, Chr^a, Bi, Bx^a, Rd, Pt^a + 15 more
High-incidence antigens	901	Vel, Lan, At^a, Jr^a, JMH, Emm, AnWj, Sd^a, Duclos, PEL, ABTI, MAM

but some appear to be dominant if an antibody to the presumed antithetical antigen has not been discovered (e.g., Ul^a, Cr^a). Some rare phenotypes appear to be inherited in a dominant manner, for example, dominant type Lu(a−b−), or in a recessive manner, for example, recessive type Lu(a−b−). Xg^a and Kx are encoded by genes on the X chromosome and are inherited in a classic X-linked manner. See Table 5–3 for the chromosomal location of genes encoding blood groups.

Expression

Some blood group antigens are also found on nonerythroid cells. Some examples are A, B, H, Kn^a (CD35), In^a (CD44), Ok^a (CD147), and Cromer-related antigens (CD55), which have a wide tissue distribution.[36,37]

The ability to culture stem cells and sort erythroid lineages and the availability of monoclonal antibodies have enabled the estimation of the timing of expression of blood group antigens during in vitro erythroid maturation. The blood group antigens appear in the following order: GPC, Kell, RhAG, LW, RhCE, GPA, band 3, RhD, Lutheran, and Duffy.[38,39]

Maturation

Several blood group antigens are not expressed or are only weakly expressed on fetal RBCs and do not reach adult levels until a person is approximately age 2. Cord RBCs do not express Le^a, Sd^a, Ch, Rg, or AnWj antigens. Antibodies to these antigens are unlikely to cause HDN, because RBC expression is a prerequisite for HDN. Expression of A, B, H, P1, I, Le^b, Lu^a, Lu^b, Yt^a, Vel, Do^a, Do^b, Gy^a, Hy, Jo^a, Xg^a, Kn, and Bg is greatly reduced on RBCs from cord blood compared to adult RBCs. In contrast, the i and LW antigens are more strongly expressed on RBCs from cord blood than on RBCs from adults. Furthermore, although adults express more LW on D-positive RBCs than on D-negative RBCs, cord RBCs express LW antigens equally regardless of D type. This information makes the testing of cord RBCs useful in antibody identification studies.

Molecular Genetic Basis

Of the 29 genes (or gene families) that encode blood group antigens, 28 have been cloned and sequenced (only the gene encoding P remains to be clarified),[40–44] and the genetic basis of many blood group antigens has been determined.[45–48] This knowledge is being applied to transfusion medicine and is discussed later in the chapter. Relevant details about blood groups and molecular knowledge are given in Chapters 6 through 8. Information concerning the genetic basis of blood group antigens can also be obtained from the Blood Group Antigen Mutation Database: www.bioc.aecom.yu.edu/bgmut/index.php.

Evolution

It has been known for many years from agglutination with human sera that blood group antigens have homologues in anthropoid apes.[49] The availability of monoclonal antibodies and molecular analysis of the gene homologues from nonhuman primates have contributed to defining the epitopes of human blood group antigens.[26,49–52] Additionally, because of the conserved nature of proteins, protein sequence comparisons are contributing to predictions about the function of human proteins (see Table 5–3). The sequencing of the genomes of many model organisms has allowed researchers to make testable inferences about protein function. The understanding of blood groups has benefited from this revolution.

Natural Knockouts

The detection of an alloantibody to a high prevalence antigen during compatibility testing or prenatal testing has led to the discovery of RBCs with null phenotypes. Such RBCs lack the specific carbohydrate or carrier protein and therefore, all blood group antigens within that system. Thus, these RBCs serve as natural knockout models and these null phenotypes have provided insights into the function of the carrier proteins.

Function

In general, the polymorphisms that we recognize as blood group antigens and that have significance in transfusion medicine do not appear to alter the function of the carrier molecule. The predicted functions are often based on the function of closely related proteins in other tissues; however, their role in the mature RBC may not be the same as in other cells, altered forms may function as recognition signals in senescent RBCs, or they may have an important role during earlier stages of erythroid development.[5]

The possible functions of the various components carrying blood group antigens can be divided into the following broad categories: contributors to membrane structural integrity, transport proteins, receptors for extracellular ligands, adhesion proteins, extracellular enzymes, complement regulatory proteins, and maintainers of surface charge in the glycocalyx (see Table 5–3).[4,45,46,53–55] Specific details can be found in the chapters that follow.

BLOOD GROUP ANTIBODIES

An *antigen* can be defined as a substance that will induce the production of antibodies, although there are certain properties of a molecule, such as foreignness, size, and chemical complexity, that are associated with increased immunogenicity. Proteins usually induce the most vigorous immune responses, followed by carbohydrates, whereas lipids and nucleic acids are usually not strong immunogens, although clinically significant antibodies specific for these types of molecules do exist (e.g., antiphospholipid antibodies and anti-DNA antibodies found in some autoimmune diseases). Most antigens require helper activity, usually in the form of cytokines, from helper T cells to induce strong antibody responses, and this helper activity is required for production of antibody classes other than IgM. Some antigens, usually carbohydrate in nature, can induce antibodies in the absence of helper T-cell activity, but these responses are primarily IgM, with little, if any, antibodies of other classes produced.

Antibodies are produced by B lymphocytes, also known as B cells. The basic antibody molecule consists of four polypeptide chains—two heavy chains of 50 to 70 kilodaltons, depending on the antibody class, and two light chains of approximately 25 kilodaltons. The two heavy chains produced by a B cell are identical, as are the two light chains. In each polypeptide chain, whether it is a heavy chain or a light chain, approximately the first 100 amino acids are known as the *variable region,* and the remainder of the polypeptide chain constitutes the *constant region,* which is identical in all antibodies of the same class. The antigen-binding site is formed by association of the variable regions of one heavy

chain and one light chain, which means that each four-chain unit has two identical antigen-binding sites. However, in most immune responses, a large number of B cells are stimulated by an antigen, and each antigen-specific B cell will produce a unique antibody, resulting in a heterogeneous response consisting of many different antibody molecules directed toward multiple sites on the antigen.

Immunogenicity

Several factors influence the ability to stimulate antibody production, including antigen size, complexity, and dose as well as host human leukocyte antigen genotype and other, as yet unidentified, susceptibility factors. Most carbohydrate-based RBC antigens are T independent and therefore tend to elicit an IgM response. The protein-based antigens usually are T dependent and induce an IgM primary response that progresses to IgG.[56] Antigen exposure usually occurs by transfusion of products containing RBCs or during pregnancy (immune antibodies) or by exposure to microbes (apparently, naturally occurring antibodies). Table 5–5 summarizes the usual type of immunoglobulin response and the potential clinical significance, in transfusion or in HDN, of selected blood group antibodies, which are listed in order of clinical significance.[36]

Clinical Significance

Antibodies recognizing antigens in the ABO blood group system are by far the most clinically significant. This is because they occur naturally in people whose RBCs lack the corresponding antigen. Other clinically significant antibodies occur in the following order, from the most commonly to the least commonly encountered in transfusion practice: anti-D, anti-K, anti-E, anti-c, anti-Fy^a, anti-C, anti-Jk^a, anti-S, anti-Jk^b. All other clinically significant antibodies occur with an incidence of less than 1% of immunized patients.[57–59] Antibodies that are considered clinically insignificant unless the antibody reacts in tests performed strictly at 37°C are anti-P1, anti-M, anti-N, anti-Lu^a, anti-Le^a, anti-Le^b, and anti-Sd^a. Other clinically insignificant antibodies that react at 37°C in the indirect antiglobulin test (IAT) are those of the Knops and Chido-Rodgers systems and anti-JMH (Table 5–6).

The incidence of a blood group antibody depends on both the prevalence in the population and the immunogenicity of the antigen. Immunized patients frequently produce multiple antibodies, and the more antibodies present, the more difficult they are to identify.

Detection and Identification

Compatibility testing (testing patient's serum against donor's RBCs) still uses techniques that were described 100 years ago for direct agglutination and 50 years ago for indirect agglutination. Even today, with our detailed understanding of blood group antigens, we have no single technical procedure able to detect all known blood group antibodies. The hemagglutination technique is simple and inexpensive, does not require sophisticated equipment, and when done correctly is sensitive and specific in terms of clinical relevance. Agglutination should be graded according to the strength of reaction, and an evaluation of the reaction strength can aid in identification of antibodies, especially when multiple antibodies are present in a serum.[33]

The first blood group antigens to be identified were those that could be agglutinated by the alloantibodies when antigen-positive RBCs were suspended in a saline medium (direct agglutination). This direct agglutination reflects the fact that these antibodies are usually IgM and detect carbohydrate antigens (ABO, P1, Le, and H antigens). Although

Table 5–5 **Characteristics of Some Blood Group Alloantibodies**

anti-A and anti-B are highly clinically significant, antibodies to the other carbohydrate antigens generally are not.

Most of the other antigens (e.g., Rh, Kell, Duffy, and Kidd) are proteins and are detected by antibodies that react in the IAT. This test detects IgG antibodies, complement attached to RBCs, or both. The sensitized RBCs are washed to remove unattached immunoglobulin (which would inhibit the antiglobulin reagent), and anti-human immunoglobulin is added. The specimen is centrifuged and examined for agglutination. The antiglobulin test can be direct or indirect. The direct antiglobulin test is used to detect RBCs sensitized in vivo, such as alloantibodies causing transfusion reactions or HDN and autoantibodies in autoimmune hemolytic anemia or cold agglutinin disease. The IAT is used to detect RBCs sensitized in vitro; for instance, antigen typing, antibody detection and identification, and compatibility testing.

To identify antibodies, serum is tested against RBCs of known phenotype by various techniques. It is sometimes helpful to treat antigen-positive test RBCs with proteolytic enzymes and chemical agents and to compare the antibody reactivity in tests against treated and untreated RBCs to aid antibody identification (Table 5–7).[47] Brief, but informative, descriptions of the technical and clinical aspects of most blood group antibodies can be found elsewhere.[33,60]

Locating Antigen-Negative Blood

Once a patient is actively immunized to an RBC antigen and produces a clinically significant alloantibody, the patient is considered immunized for life and must be transfused with antigen-negative RBCs, even if the antibody is no longer detectable. Patients with passively acquired antibody (e.g., neonates and recipients of plasma products, Rh immune globulin, or IVIgG) are not actively immunized and may be transfused with antigen-negative RBCs only while the passive antibody is still present. Selection of blood for transfusion of a patient with blood group alloantibodies is the joint responsibility of the staff at the transfusion service, the donor center, and the patient's physician. Thus, it is very important that there be communication regarding the number of units of RBC products required and the time frame involved. Figure 5–2 is a flow chart that outlines the process for locating blood. Table 5–8 lists the prevalence of donors whose RBCs lack selected antigens.

To locate antigen-negative blood for transfusion, it is not necessary to identify an antibody to a low-prevalence antigen detected in the recipient's blood during compatibility testing, because another unit of donor blood is highly unlikely to be positive for the same uncommon antigen. In contrast, if an antibody to a low-prevalence antigen is detected in the serum of a pregnant woman, identification of the antibody or determination of its reactivity with paternal RBCs is required to predict the likelihood and severity of HDN in the baby. Locating blood for exchange transfusion is not difficult, for the reason previously described.

If a patient's serum contains alloantibodies to a high-prevalence antigen, blood for transfusion may be very difficult to locate. Whether the investigation is for transfusion purposes or for prediction of HDN, the antibody should be identified. The identification aids in both the assessment of its clinical significance and the location of appropriate blood for transfusion. Family members, in particular siblings, are

Table 5–7 Reactivity of Antigen-Positive Red Blood Cells after Treatment with Ficin/Papain or DTT

Ficin/Papain	Dithiothreitol (200 mM)	Possible, Antibody Specificity

Patient has clinically significant antibody?
No
Yes
Use routine crossmatch procedure
Calculate incidence
Multiply negative frequency for each antigen × 100
Example: 0.91 (K) × 0.48 (S) = 0.436 × 100 = 44%
Calculate number of antigen-negative donors:
100 ÷ 44 = 1 in 3 units will lack K and S
Antigen negative available from hospital inventory?
Yes
No
Screen inventory at donor center
Test siblings/family
Call in phenotyped donors
Check frozen inventory
Examine rare donor file (last resort)
Use autologous
Crossmatch antigen-negative units

Figure 5–2 Flow chart for locating antigen-negative blood.

the first source to investigate for antigen-negative units. Most national blood donor centers can often assess national and international Rare Donor Registries and can help provide the appropriate antigen-negative blood.

COMPATIBILITY PROCEDURES

Most laboratories follow recommendations made by the American Association of Blood Banks,[61] and all must comply with regulations of state and federal agencies. Routine approaches to compatibility testing involve testing a blood sample from a prospective recipient for ABO and D blood groups and for the presence of blood group antibodies. In most cases, no unexpected antibodies are detected, and donor RBCs of appropriate ABO and D blood type are selected for transfusion. A sample of the donor's RBCs may be tested (crossmatched) with the patient's serum by means of either an immediate spin procedure or the IAT. Alternatively, the blood can be issued without direct cross-testing if a computer check is performed.[33] Any blood typing problems should be resolved, and when antibodies are detected, they should be identified. Knowing the specificity of an antibody helps establish whether it is likely to be clinically significant and determine the approach necessary to provide an adequate supply of compatible blood. Once an antibody has been identified, antigen-negative RBC products selected for transfusion should be tested with the patient's serum by the IAT to ensure compatibility.

It is important not to delay surgery or transfusion unnecessarily by attempting to obtain antigen-negative RBCs for patients with clinically insignificant antibodies. Also, in hemolytic anemia due to warm-reactive autoantibodies, compatibility may be difficult to demonstrate. The important issue is to be sure that there are no underlying, clinically significant alloantibodies. This fact can be determined with autologous or homologous autoabsorptions,[33] which require extra time and, possibly, the services of an immunohematology reference laboratory. It is helpful to remember that patients without a history of immunization (transfusion or pregnancy) are unlikely to have underlying alloantibodies. Unfortunately, a patient's transfusion history is not always reliable, because many patients are unaware or forget that they have received transfusions.[62]

CHOICE OF ANTIGEN-NEGATIVE BLOOD FOR DISEASES REQUIRING LONG-TERM TRANSFUSION THERAPY

Transfusion management of patients who require long-term transfusion therapy, in particular patients with sickle cell anemia, has been the subject of controversy and debate.[63,64] There is still no consensus as to the best and most practical approach, although the goal is to provide blood with maximal survival. In addition to the traditional practice of providing antigen-negative blood only after the patient has made an antibody, approaches that have been adopted

Table 5–8 **Antigen-Negative Incidence—Common Polymorphic Antigens***

System	Antigen	Incidence of Antigen Negativity: White	Black
Rh	D	0.15	0.08
	C	0.32	0.73
	E	0.71	0.78
	C	0.20	0.04

	N	0.30	0.25
	S	0.48	0.69
	S	0.11	0.06
	M,S	0.15	0.19
	M,s	0.01	0.02
	N,S	0.1	0.16
	N,s	0.06	0.02
P	P1	0.21	0.06
Lewis	Le^a	0.78	0.77
	Le^b	0.28	0.45
Lutheran	Lu^a	0.92	0.95
	Lu^b	<0.01	<0.01
Kell	K	0.91	0.98
	K	0.002	<0.01
	Kp^a	0.98	>0.99
	Kp^b	<0.01	<0.01
	Js^a	>0.99	0.80
	Js^b	<0.001	0.01
Duffy	Fy^a	0.34	0.90
	Fy^b	0.17	0.77
Kidd	Jk^a	0.23	0.08
	Jk^b	0.26	0.51
Dombrock	Do^a	0.33	0.45
	Do^b	0.18	0.11
Colton	Co^a	<0.01	
	Co^b	0.90	

*To calculate the incidence of compatible donors, multiply the incidence of antigen-negative donors for each antibody, e.g., the incidence of K, S, and Jk^a negative donors in the general donor pool is (0.91) × (0.48) × (0.23) = 0.10 in 100, or 1 in 1000.

include providing phenotype-matched blood after the first antibody is made; providing blood matched for D, C, E, and K antigens; providing fully antigen-matched blood (i.e., matched for D, C, E, c, e, K, Fy^a, Fy^b, Jk^a, and Jk^b antigens); and providing blood based on ethnic background combined with antigen matching for D, C, E, and K.[65–70]

Clearly, if the objective is to prevent immunization to blood group antigens, initial phenotype matching is the logical approach; however, this approach does not prevent the production of antibodies to high-prevalence antigens, such as U, Js^b, Cr^a, hr^S, and hr^B. The decision as to whether the blood donor community can support this approach lies with the directors of the transfusion service and of the donor center that supplies the blood. Providing phenotypically matched RBC products is logistically difficult and expensive. Although from the patient's perspective it is desirable to be transfused only with phenotype-matched blood, the community may not be able to support that approach. Indeed, in some regions, it is a challenge to provide antigen-negative blood to patients who have already made the antibodies. Extensive screening for antigen-negative donors may be realized with the advent of microarray technology.

COMPLICATIONS OF TRANSFUSION

As previously described, physicians in some locations may choose to provide phenotype-matched blood for patients with sickle cell anemia who undergo long-term transfusion therapy. Because the incidences of antigens differ in various ethnic groups, blood for these patients is most likely to be found among African American donors, whose RBCs more commonly lack C, E, K, S, Fy^a, Fy^b, and Jk^b antigens than the RBCs of white donors.[70] However, it is worth noting that RBCs from African American donors are more likely (approximately 1 in 5) to express antigens for which we do not routinely test, such as VS, Js^a, Go^a, and DAK.[71] Thus, because all these antigens are immunogenic but are not present on screening cells, it is recommended in this group of patients that blood be crossmatched using the IAT in preference to performing a computer match. This crossmatching approach would prevent a potential transfusion reaction due to antibodies such as anti-VS, anti-Js^a, anti-Go^a, and anti-DAK.

Although current pretransfusion practice has drastically reduced the incidence of hemolytic transfusion reactions, they still occur. The single most common cause of a hemolytic transfusion reaction is clerical error. It should be noted that several conditions mimic hemolytic transfusion reactions; they are summarized in Table 5–9. Additional details can be found in the review by Beauregard and Blajchman.[72]

HEMAGGLUTINATION AS AN AID IN DIAGNOSIS

Hemagglutination can be used to diagnose syndromes that are caused by the absence of a component carrying blood group antigens (null phenotypes). For example, an absence of the Rh proteins causes stomatocytosis and compensated hemolytic anemia (Rh syndrome),[30,73,74] and an absence of Xk protein causes the McLeod syndrome.[28,75–77] These individuals can be identified with a simple test of their RBCs with antibody to common Rh antigens and to Kx antigen, respectively. RBCs and white blood cells (WBCs) from patients with leukocyte adhesion deficiency II (also known as congenital disorder of glycosylation) lack antigens that are dependent on fucose. Thus, the RBCs have a Bombay, Le(a−b−) phenotype. Their WBCs lack sialyLe^x, which explains the high WBC count and infections in these patients.[78,79]

APPLICATIONS OF DNA-BASED ASSAYS IN TRANSFUSION MEDICINE

The astounding pace of growth in the field of molecular biology and in the understanding of the genetic changes associated with most blood group antigens and phenotypes enables us to consider identification of blood group antigens and antibodies using nucleic acid-based approaches. Indeed, the knowledge is already being applied to help resolve some long-standing clinical problems that cannot be resolved by classical hemagglutination.

Table 5–9 **Causes of Apparent in Vivo Hemolysis**

Immune Causes
ABO incompatibility
Clinically significant alloantibody
Anamnestic alloantibody response
Autoimmune hemolytic anemia
Cold agglutinin disease
Hemolytic disease of the newborn
Drug-induced hemolytic anemia
Polyagglutination (sepsis T-active plasma)
Paroxysmal cold hemoglobinuria
Thrombotic thrombocytopenic hemolytic uremia syndrome (a microangiopathic process)

Nonimmune Causes
Mechanical
- Poor sample collection
- Small-bore needle used for infusion
- Excessive pressure during infusion
- Malfunctioning blood warmer
- Donor blood exposed to excessive heat or cold
- Urinary catheter
- Crush trauma
- Prosthetic heart valves
- Aortic stenosis
- March hemoglobinuria

Microbial
Sepsis
- Malaria
- Contamination of donor blood

Chemical
Inappropriate solutions infused
- Drugs infused
- Serum phosphorus <0.2 mg/dL
- Water irrigation of bladder
- Azulfidine
- Dimethyl sulfoxide
- Venom (snake, bee, brown recluse spider)
- Certain herbal preparations, teas, enemas

Inherent Red Blood Cell Abnormalities
Paroxysmal nocturnal hemoglobinuria
- Sickle cell anemia
- Spherocytosis
- Hemoglobin H
- Glucose-6-phosphate dehydrogenase deficiency

Although direct and indirect hemagglutination tests have served the transfusion community well for more than 100 and more than 50 years, respectively, in some aspects, hemagglutination has limitations. For example, it gives only an indirect measure of the potential complications in an at-risk pregnancy, it cannot indicate *RHD* zygosity in D-positive people, it cannot be relied on to type some recently transfused patients, and it requires the availability of specific reliable antisera. The characterization of genes and determination of the molecular basis of antigens and phenotypes has made it possible to use the polymerase chain reaction[80,81] to amplify regions of DNA of interest to detect alleles encoding blood groups. The knowledge can also be applied to express antigens in heterologous systems as a first step to detect and identify blood group antibodies in a single, objective, automated assay.

DNA Basis of Blood Group Antigens

Once a gene is shown to encode a protein that carries a blood group, focused analysis of people with known serologically defined antigen profiles is used to determine the molecular basis of variant forms of the gene. This approach has been extremely powerful because antisera-based definitions of blood groups readily distinguish variants within each blood group system. The molecular basis associated with many blood group antigens has been determined over a relatively short period.[30,46,54,73,82–99] The available wealth of serologically defined variants has contributed to the rapid rate with which the genetic diversity of blood group genes has been revealed. Initially, molecular information associated with each variant was obtained from only a small number of samples and applied to analysis with the hopeful assumption that the molecular analysis would always correlate with RBC antigen typing. With the gathering of more information it became obvious that several molecular events can result in discrepant genotype and RBC phenotype (some are listed in Table 5–10). Furthermore, analyses of the null phenotypes have demonstrated that multiple, diverse genetic events can give rise to the null phenotype, for example, for Rh,[30,73] Kell,[100] and Jk systems,[101] and the p phenotype.[102]

Antigen Identification by DNA Testing

Although there are many molecular events that give rise to blood group antigens and phenotypes, the majority of genetically defined blood group antigens are the consequence of an SNP. Thus, simple DNA-based assays can be used to identify defined SNPs in genes encoding blood groups. Innumerable DNA-based assays have been described to detect specific blood group SNPs. They include polymerase chain reaction (PCR)-restriction fragment length polymorphism (RFLP), allele-specific (AS)-PCR, sequence-specific (SS)-PCR as single or multiplex assays, real-time quantitative PCR (Q-PCR; RQ-PCR), a single nucleotide dye terminator extension method, and high throughput microarray technology. The PCR-RFLP, AS-PCR, and SS-PCR assays can be visualized in a gel or by electropherogram printouts. Semi-automated methods that use a specific tag attached to the primers, which can then be analyzed in a digital readable format by a mass-spectrometer or pyrosequencer, have tremendous potential in the clinical laboratory. Another exciting opportunity is the use of microchip technology for the purpose of antigen identification.[103,104] The process uses a "chip," which is composed of spots of DNA from many genes attached to a solid surface in a gridlike array. The fluorescent-labeled cDNA or DNA with a sequence that matches the sequence of one of the gene fragments adheres and can be detected. The system is most frequently used for studying genes involved in regulation and expression.[105] However, it is now also being used to analyze specific blood group genes. Some clinical applications of DNA analysis for blood groups are listed in Table 5–11.

In the Transfusion Setting

FOR TRANSFUSION-DEPENDENT PATIENTS

Certain medical conditions, such as sickle cell disease, thalassemia, autoimmune hemolytic anemia, and aplastic

Table 5–10 Examples of Events That Confound Analysis of Genotype and Phenotype

Event	Mechanism	Blood Group Phenotype
Promoter mutation	Nucleotide change in GATA box	Fy(b–)

	Absence of protein 4.1	Weak expression of Ge antigens
Modifying gene	*In(LU)*	Lu(a–b–)
	In(Jk)	Jk(a–b–)

anemia, often require chronic blood transfusion. In this situation or when a patient receives a massive transfusion, the presence of donor RBCs in the patient's peripheral blood makes RBC phenotyping by conventional hemagglutination techniques complex, time-consuming, and possibly inaccurate. Indeed the interpretation of RBC typing results of multitransfused patients, based on such parameters as number of units transfused, length of time between transfusion and sample collection, and size of patient (the "best guess"), is often incorrect.[106] It is desirable to determine the blood type of a patient as part of the antibody identification process, and molecular DNA approaches are being used to type patients to overcome this limitation of hemagglutination. Interference or false results from transfused donor WBCs surviving in the recipient's circulation depends on the design of the assay used.[107] PCR assays designed for transfusion medicine testing do not detect post-transfusion DNA chimerism, and blood group determinations can reliably be made using DNA prepared from a blood sample collected after the patient has received recent chronic or even massive transfusions.[108–111] Determination of a patient's blood type by analysis of DNA is particularly useful when a patient who is transfusion-dependent has produced alloantibodies. This is because identification of the patient's probable phenotype allows the laboratory to determine to which antigens the patient can and cannot respond to make alloantibodies.

Table 5–11 Clinical Applications of DNA Analysis for Blood Group Antigens

- To type patients who have been recently transfused
- To type patients whose RBCs are coated with immunoglobulin
- To identify a fetus at risk for hemolytic disease of the newborn
- To determine which phenotypically antigen-negative patients can receive antigen-positive RBCs
- To type donors for antibody identification panels
- To type patients who have an antigen that is expressed weakly on RBCs
- To determine *RHD* zygosity
- To mass screen for antigen-negative donors
- To resolve blood group A, B, and D discrepancies
- To determine the origin of engrafted leukocytes in a stem cell recipient
- To determine the origin of lymphocytes in a patient with graft-versus-host disease
- For tissue typing
- For paternity and immigration testing
- For forensic testing

For Patients Whose RBCs Have a Positive DAT. DNA-based antigen typing of patients with autoimmune hemolytic anemia, whose RBCs are coated with immunoglobulin, is valuable when available diagnostic antibodies require the IAT and IgG removal techniques (e.g., EDTA-acid-glycine, chloroquine diphosphate) are not effective at removing bound immunoglobulin, or when these techniques destroy the antigen of interest.

For Donors. DNA-based assays can be used to antigen-type donor blood both for transfusion and for antibody identification reagent panels. This is particularly useful when antibodies are not available or are weakly reactive. A good example is the Dombrock blood group polymorphism, where DNA-based assays[112–114] are used to type patients and donors for Do^a and Do^b to overcome the problem of not having reliable typing reagents. Furthermore, the newer DNA technologies have the potential for screening pools of DNA for rare blood types and thereby increasing the number of donors that can be tested. As automated procedures attain higher and faster throughput at lower cost, typing of blood donors by DNA-based assays is likely to become more widespread, revolutionizing the provision of antigen-negative blood to patients.

With donor DNA-based typing, the presence of a grossly normal gene whose product is not expressed on the RBC surface would lead to the donor being falsely typed as antigen-positive, and although this would mean loss of an antigen-negative donor, it would not jeopardize the safety of the patient in blood transfusion practice.

IN THE PRENATAL SETTING

Hemagglutination titers give only an indirect indication of the risk and severity in HDN. Thus, antigen typing by DNA-based assays has particular value in the prenatal setting to determine whether the fetus has inherited the paternal antigen of clinical relevance. If the fetus is predicted to be antigen-negative, the fetus is not at risk for HDN and the mother need not be aggressively monitored.

Specific criteria should be met before initiating fetal DNA testing. The mother's serum contains an IgG antibody of potential clinical significance and the father is heterozygous for the gene encoding the antigen of interest (or paternity is in doubt). It is helpful to know the ethnic origin and to genotype both mother and father concurrently with the fetus to confirm the inheritance and to identify potential variants that could influence interpretation of the test results.

Fetal DNA can be isolated from cells obtained by invasive procedures such as amniocentesis or chorionic villus sampling and by noninvasive procedures from trophoblasts collected by transcervical sampling[115–117] and from fetal erythroblasts isolated from the maternal circulation.[118] Remarkably, cell-free fetal-derived DNA can be extracted from maternal serum or plasma[119–122] and *RHD* typing is possible.[120,123–129] Use of cell-free fetal DNA from maternal plasma has overcome concerns that fetal lymphocytes from previous pregnancies can persist in maternal blood[130] or skin[131] for years. This is not a problem with cell-free fetal DNA because it clears the maternal circulation within 3 days of termination of the pregnancy.[120,121] Fetal DNA obtained from maternal plasma appears to be less stable and reports vary regarding optimal sample storage.[120,129] Large-scale trials and standardization of protocols are still needed; however, it is likely that determination of fetal *RHD* using this noninvasive procedure will become routine clinical practice. *RHD* testing for D expression is the prime target because, at least in the majority of white individuals, the D-negative mother has a complete deletion of *RHD*, thereby permitting detection of the paternally derived fetal *RHD* gene. For analysis of the inheritance of blood group antigens determined by SNPs (e.g., K/k) rather than by the presence or absence of the gene, a sample source that contains primarily fetal DNA (e.g., amniocytes) is preferred. When isolating fetal DNA from maternal plasma, proper positive controls that test for the presence of fetal DNA are critical. Y chromosome markers are useful when the fetus is a male, but polymorphic paternal markers are needed in the case of a female.

DNA analysis for the prediction of fetal D phenotype is based on detecting the presence or absence of portions of *RHD*. A prerequisite to the accurate interpretation of DNA analysis in clinical applications is the extensive molecular characterization of apparently identical phenotypes in mother and fetus. The Rh blood group system is complex, and many hybrid genes have been described. For example, in Europeans, the molecular basis of the D-negative phenotype was, with few exceptions, associated with deletion of the entire *RHD*, until a study of serologically D-negative samples revealed nine novel *RHD* gene-positive haplotypes.[95,132] Approximately one third of Japanese D-negative people have an intact but inactive *RHD*. The majority of D-negative Africans and approximately one quarter of D-negative African Americans have an inactive *RHD* pseudogene (*RHDΨ*), and many others have hybrid *RHD-CE-D* genes.[133] These hybrid genes complicate DNA testing and can lead to false results if they are not understood by the investigator.[30,74]

When recommendations for clinical practice are based on molecular analyses, it is important to remember that, in rare situations, a genotype determination will not correlate with antigen expression on the RBC (see Table 5–10).[48,95–97,133–138] If a patient has a grossly normal gene that is not expressed (usually a null phenotype), he or she could produce an antibody if transfused with antigen-positive blood. When feasible, the appropriate assay to detect a mutation that silences a gene should be part of the DNA-based testing (e.g., GATA box analysis with *FY* typing,[137] presence of *RHD* pseudogene with *RHD* typing,[133] and exon 5 analysis with *GYPB(S)* typing).[139] Also, it is important to obtain an accurate medical history for the patient because with certain medical treatments, such as stem cell transplantation and kidney transplants, typing results in tests using DNA from different sources (such as WBCs, buccal smears, or urine sediment) may differ. Thus, thought should be given as to the purpose of the testing when establishing standard operating procedures for use in the clinical laboratory.

Before interpreting the results of DNA testing, it is important to obtain an accurate medical history and to establish if the study subject is a surrogate mother, if she has been impregnated with nonspousal sperm, or if she has received a stem cell transplant. This information, although critical, is often not provided. For prenatal diagnosis of a fetus at risk of HDN, the approach to genotyping should err on the side of caution.

When performing any blood group DNA analysis in the prenatal setting, determining the *RHD* status of the fetus, in addition to the test being ordered, can be important. If the fetus has a normal *RHD,* there is no need to provide Rh-negative blood for intrauterine transfusions. This is especially true if the mother has anti-c and fetal DNA is being typed for *RHc*.

Antibody Identification

In addition to the value of typing donors for antibody identification panels when appropriate antibodies are not available, DNA analyses are being used to aid in the identification of Dombrock (anti-Hy, anti-Jo^a), Knops (anti-Kn^a, anti-Sl^a, and anti-McC^a), and Rh (anti-hr^S, anti-hr^B) antibodies. Determination of the phenotype of the patient allows more accurate classification in Dombrock and Knops blood group systems.

DNA can be transfected into cells and grown in tissue culture to express blood group antigens. Indeed, single-pass (Kell) and multipass (Duffy) proteins have been expressed in high levels in mouse erythroleukemic cells or 293T cells and detected by human polyclonal antibodies.[140] Similar experiments have been performed on Lutheran antigens.[141] Thus, it is theoretically possible to produce a panel of cell lines expressing individual proteins for development of an automated, objective, single-step antibody detection and identification procedure. Such an approach would eliminate the need for antigen-matched, short-dated, potentially biohazardous RBC screening and panel products derived from humans. However, although promising, some major hurdles are yet to be overcome; for example, antigens from all blood group systems must be expressed at levels that are at least equivalent to those on RBCs and the detection system should have low background levels of reactivity. The highly clinically significant Rh antigens are proving difficult to express in adequate levels.

Recombinant cells expressing blood group antigens can be used for adsorption of specific antibodies as part of antibody detection and identification procedures, or prior to crossmatching if the antibody is clinically insignificant. In addition, genes can be engineered to express soluble forms of antigens for use in antibody inhibition, again as part of antibody detection and identification procedures, or prior

to crossmatching.[142–144] Concentrated forms of recombinant CR1 (CD35) would be valuable to inhibit clinically insignificant antibodies in the Knops system, thereby allowing a compatible crossmatch. So far it has proven difficult to prepare the recombinant material in sufficient quantity to be of practical use.

General Considerations

The quality of DNA may be compromised in clinical samples that are not stored correctly, but this is often overcome by restricting the size of the amplified PCR product.[145] To maximize the value of DNA analysis in transfusion medicine, several areas of expertise are desirable when using molecular approaches to identify blood groups: an expertise in antibody identification, a knowledge of and ability to troubleshoot techniques, a knowledge of the genes encoding blood group antigens and their variant forms, an expertise in interpretation of the PCR-based assays used, and knowledge about the clinical significance of blood group alloantibodies.

Hemagglutination has identified many phenotypic variants encoded by *RHD*, *RHCE*, or hybrids of the two, and molecular analysis has revealed remarkable variation within the variants. Of clinical concern is the distinction, difficult to make serologically, between weak partial D and weak D phenotypes because the former may make alloantibodies to D, whereas the latter are unlikely to do so. Numerous partial D and weak D phenotypes have been defined at the molecular level,[30,73,132,138,146] and it is anticipated that this information, together with clinical (and serologic) data, will be used to guide transfusion and testing policy for patients and donors.[74]

Molecular analysis of samples with aberrant e and E antigen expression have highlighted the complexity of polymorphisms. In whites, variant e antigen expression was associated with the presence of a 48G>C nucleotide change in *RHCE*.[147] Depressed e antigen expression in black persons, which is often associated with the loss of hr^S antigen, results from different molecular backgrounds, many which have a Met238Val substitution in the Rhce protein.[148,149] To identify serologically, with certainty, that a person is truly hr^S-negative and to screen for compatible donors has always been challenging due to the lack of suitable reagents. Thus, the possibility of using a molecular approach to fulfill the transfusion requirements of such patients will quickly have a positive impact by providing the means to identify those patients at risk of making anti-e-like antibodies and a valuable screening tool for donors.

Many new *ABO* alleles have been defined,[82–84] and *ABO* genotyping is a useful clinical tool for the resolution of typing discrepancies and is especially valuable for distinguishing acquired variant phenotypes from inherited ones. DNA analysis makes it possible to define a person's ABO genotype without laborious family studies. However, improvements in testing and population studies are needed to ensure detection of the multitude of *ABO* alleles now known. DNA-based analyses will be useful to explain apparent discrepancies in typing blood donors for certain ABO subgroups that may otherwise be reportable to the FDA. In summary, the multitude of ABO and Rh alleles indicates that a large number of people from a variety of ethnic backgrounds need to be studied to determine the occurrence of particular genotypes and to establish more firmly the correlation between blood group genotype and phenotype.

Our growing understanding of the molecular basis underlying blood group polymorphisms can be used to develop automated systems for antigen typing and for antibody detection and identification. Development of DNA microarray technology continues at a rapid rate. Thus, it should soon be possible to analyze major and many minor blood group alleles on a single synthetic chip that is smaller than the head of a pin.

Currently, DNA-based assays provide a valuable adjunct to the classic hemagglutination assays. Molecular analyses have the advantage that genomic DNA is readily available from peripheral blood leukocytes, buccal epithelial cells, and even cells in urine, and it is remarkably stable. The current disadvantage is that the genotype determined on DNA may not, in some instances, reflect the RBC phenotype.

The next three chapters provide details about specific blood group antigens. Chapter 6 focuses on the ABO system and other carbohydrate antigens. Chapter 7 concentrates on the Rh, Kell, Duffy, and Kidd systems, in which the corresponding antibodies are potentially highly clinically significant. Chapter 8 describes aspects of the other blood groups.

Many websites have useful information about blood group systems. Some URL addresses that may be of interest to the reader are as follows:

Chapter 6

ABO and Related Antigens and Antibodies

Connie M. Westhoff • Marion E. Reid

This chapter summarizes current knowledge of the blood groups composed of terminal carbohydrate moieties, the ABO, H, Lewis, Ii, and P systems (International Society of Blood Transfusion [ISBT] system or collection numbers given in parentheses). The antigens are the products of the action of glycosyltransferase enzymes, and they share biochemical synthesis pathways and precursor framework oligosaccharide molecules. The antigens are carried on large oligosaccharide chains covalently linked to proteins (glycoproteins), lipids (glycolipids), or both on the red blood cell (RBC). In addition, some are expressed on tissues, and soluble forms can be found in various secretions and excretions.

ABO AND Hh SYSTEMS (ISBT SYSTEMS 001 AND 018)

History

ABO was the first blood group system to be discovered. In 1900, Landsteiner mixed sera and RBCs from his colleagues and observed agglutination.[1] On the basis of the agglutination pattern, he named the first two blood group antigens A and B, using the first two letters of the alphabet. RBCs not agglutinated by either sera were first called type C but became known as "ohne A" and "ohne B" (*ohne* is German for "without") and finally O. Landsteiner received the Nobel Prize in 1930, 30 years after the discovery of the ABO blood groups.

Unfortunately, administering transfusions based on agglutination reactions was largely ignored, and surgeons continued performing direct donor-to-patient blood transfusions. This practice provided many opportunities to observe symptoms of severe and fatal hemolytic transfusion reactions. Not until methods were developed to store and preserve blood (1914–1917) did blood transfusion move to the blood bank environment, and World War I saw the first large-scale transfusions based on serologic ABO selection of donors.[2]

Antigens

The ABO antigens were biochemically characterized in the 1950s and 1960s (reviewed in Yamamoto[3]) as carbohydrate structures on glycoproteins and glycolipids. The ABO system consists of four antigens with ISBT numbers—A, B, A,B, and A_1—but there are additional subgroups (e.g., A_2, A_3, A_X, A_{el}, B_3), and Hh is a separate system.[4] The antigens are synthesized in a stepwise fashion by glycosyltransferase enzymes that sequentially add specific monosaccharide sugars in specific linkages to a growing oligosaccharide precursor chain. The terminal sugar determines antigen specificity: an *N*-acetylgalactosamine residue results in expression of the A antigen, and a terminal galactose residue is responsible for the B antigen. These structures are similar, differing only in that A antigen has a substituted amino group on carbon 2 (Fig. 6–1). The precursor substrate for A and B antigens is the H antigen (Fig. 6–2). The terminal fucose in $\alpha(1,2)$ linkage to galactose is responsible for H antigen specificity, and large amounts of H are present on group O RBCs, because H is not converted to A or B. Some H antigen precursor also remains on A and B RBCs, listed as follows in descending order of frequency: A_2, B, A_2B, A_1, A_1B.

RBC membrane proteins carry well over 2×10^6 A, B, and H antigens (ABH) combined per RBC, and most (80%) are located on the major integral membrane protein, band 3 (anion exchanger 1, or AE1), which is the RBC $Cl^-HCO_3^-$ anion exchanger. In addition, the glucose transporter, Rh-associated glycoprotein (RhAG), and aquaporin-1 (Colton) also carry A, B, and H, but in smaller amounts (reviewed in Lowe[5]). A, B, and H antigens are also found in lesser amounts as lipid-linked glycoconjugates associated with the RBC membrane via a ceramide moiety.

After their discovery on RBCs, the ABH antigens were also found on many tissues. Large amounts are expressed on endothelial and epithelial cells of the lung and gut and on the epithelial cells of the urinary and reproductive tracts; hence, they are called *histo-blood group antigens.* ABH antigens are also found in secretions (particularly saliva) and fluids (milk and urine) of 80% of the population who have the secretor (Se) phenotype.[6]

ABH antigens are also found on platelets. The amount of A or B antigen on platelets varies between individuals, with approximately 8% of blood group A and 10% of B donors reported to have "high" level expression.[7] Thus, ABO incompatibility can compromise the outcome in platelet transfusions. Recent studies have refocused attention on the interesting observation that platelets from donors with an A_2 phenotype lack both A and H antigens.[8,9] The biochemical basis for the lack of A antigen is not yet known, but this observation has implications for transfusion practice in that approximately 20% of group A platelets would be from A_2 donors (see incidence of A_2 phenotype). These platelets would be appropriate for "universal" use, and platelets from A_2 donors may also be a superior product for patients undergoing A/O major mismatch allogeneic progenitor cell transplantation.[9]

As tissue antigens, ABH are important in solid organ transplantation. Recipient antibodies react with antigens on the transplanted organ, and complement activation at the surface of endothelial cells results in rapid destruction and

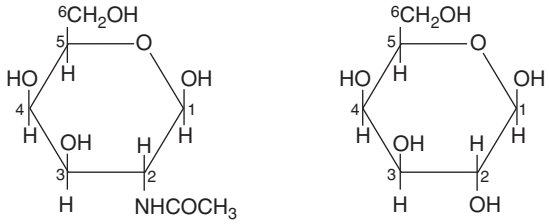

Figure 6–1 Terminal carbohydrates that define the A and B antigens. The terminal galactose residues differ only in that the A antigen has a substituted amino-acetyl group on carbon number 2.

acute rejection.[10] However, successful transplantation across ABO barriers is possible, particularly with blood group A_2 to O, and combined with current immunosuppressive and pretreatment regimens (reviewed by Rydberg[11]). As observed for platelets, the absence of A antigen on tissues of group A_2 indicates significant lack of A_2-transferase activity in non-erythroid tissues.[12,13]

The incidence of ABO blood groups differs in populations (Table 6–1).[14] Group B is found twice as frequently in African Americans and Asians as in white persons. Group A subgroups are more common than group B subgroups, and A_2 has an average incidence of 20% of group A patients.[15] Subgroup A_2 is rare in Asians.

Inherited and Acquired ABH Antigen Variants

Subgroups of A and B have weaker expression of the respective antigens. The difference between A_1 and A_2 is quantitative, because the number of A antigens is reduced on A_2. The difference is also qualitative, because there are structural differences in the branching of the oligosaccharide chains. The structural difference explains why A-subgroup individuals often make anti-A_1. The reagent *Dolichos biflorus* lectin distinguishes A_1 from A_2 and other A subgroups.

Acquired B antigen results from the action of bacterial deacetylase, an enzyme that can remove an acetyl group from the A-terminal sugar, *N*-acetylgalactosamine. Galactosamine is similar to galactose, the B-specific terminal residue, and anti-B reagents can cross-react with the deacetylated structure.[16] Acquired B usually occurs in individuals suffering from colon or rectal carcinoma, intestinal obstruction, or infections involving gram-negative bacteria from the gut. It is transient and, because the acquired B develops at the expense of A antigen, the phenotype is found only in group A patients. There is a report of a transfusion fatality in a group A patient mistyped as AB because of acquired B who was transfused with group AB blood.[17]

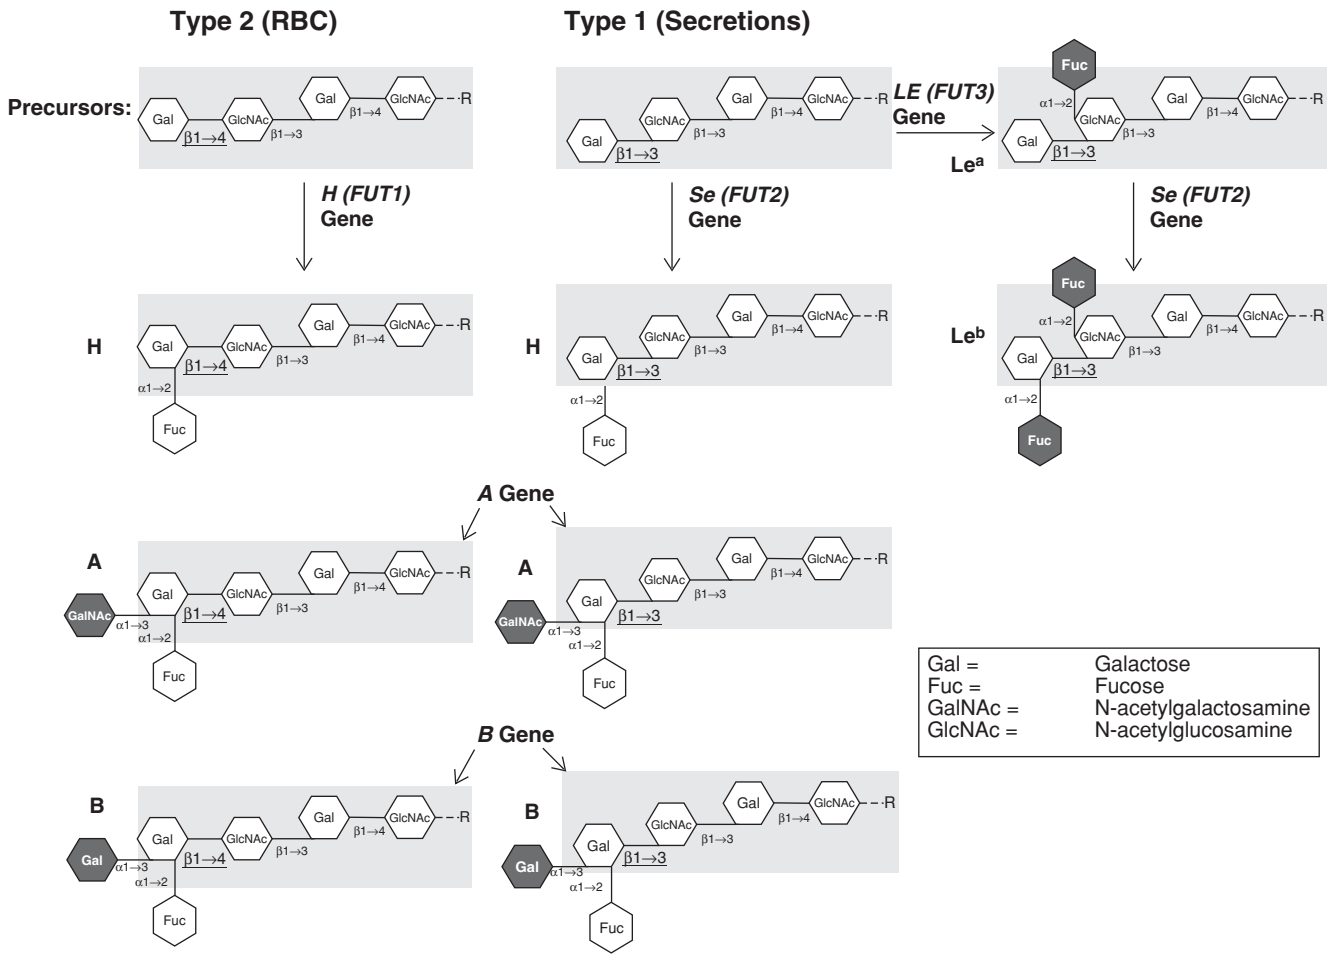

Figure 6–2 Synthesis of A, B, and H, and Lewis antigens. Oligosaccharide precursor core type 1 and type 2 structures differ only in the linkage between the terminal galactose (Gal) and the ***N***-acetylglucosamine (GlcNAc), shown underscored. Terminal carbohydrates that define the antigens are shown in black.

Table 6–1 ABO Blood Groups and Incidence			
	Incidence (%)		
Phenotype	White	African American	Asian
A_1	34	19	27
A_2	10	8	Rare
B	9	19	25
A_1B	3	3	5
A_2B	1	1	Rare
O	44	49	43

A or B antigen expression can weaken in patients with acute leukemia or stress hematopoiesis. Chromosomal deletions and lesions that involve the ABO locus can result in the loss of transferase expression in the leukemic cell population. A decrease in A or B antigen expression, when found without a hematologic disorder, can be prognostic of a preleukemic state. In stress hematopoiesis, the higher turnover and early release from the bone marrow results in reduced branching of the carbohydrate chains, causing weakened expression.[18]

Rare Bombay phenotype RBCs (first reported in Bombay, India) lack H antigen; consequently, without H precursor, they also lack A and B antigens. These RBCs type routinely as group O, designated O_h, and the serum contains potent anti-H in addition to anti-A and anti-B.[18,19]

ABO Genes

In 1959, Watkins and Morgan[20] correctly suggested that the genes for the carbohydrate ABO determinants actually encoded enzymes responsible for the assembly of the subunits. The ABO locus encodes the A and B glycosyltransferases, which were mapped by linkage analysis to chromosome 9q34.[21] Researchers cloned the A-glycosyltransferase in 1990 by exploiting the fact that some tumors have increased expression of ABH antigens and the corresponding glycosyltransferase. Soluble enzyme was isolated from lung tissue for amino acid sequencing,[22] and complementary DNA libraries from gastric carcinoma and colon adenocarcinoma cell lines from individuals with different ABO phenotypes were screened and sequenced to determine the molecular differences among the transferases.[23,24]

The ABO glycosyltransferase gene contains seven exons and spans approximately 18 to 20 kb.[25] It encodes a 354-amino acid, 41-kD transferase that has a short N-terminal region, a hydrophobic transmembrane segment for retention in the Golgi membrane, and a large C-terminal, catalytically active domain (Fig. 6–3). The glycosyltransferase enzymes are membrane-bound in the lumen of the Golgi,[26] and glycosylation of membrane proteins takes place during transit through the Golgi. Some soluble enzyme is also found in body fluids and plasma and is derived from the membrane-bound enzyme through proteolysis that cleaves the catalytic domain from the membrane-spanning domain.[27]

A and B transferases

The A and B transferase enzymes differ by only 4 of 354 amino acids, Arg176Gly, Gly235Ser, Leu266Met, and Gly268Ala. The last two, residues 266 and 268, are primarily

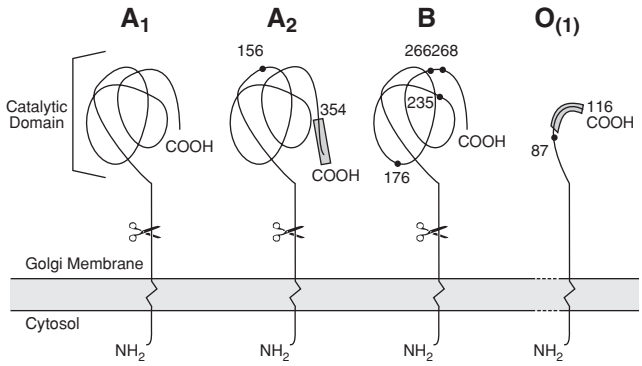

Figure 6–3 Model of the glycosyltransferases and their location in the lumen of the Golgi. Proteolytic cleavage, shown as *scissors,* generates the soluble enzyme found in body fluids and plasma. The *boxed areas* on the A_2 and O_1 glycosyltransferases indicate the altered protein sequence that results from the frameshift gene mutations. (The O truncated enzyme probably does not reach the Golgi membrane.)

responsible for the substrate specificity (see Fig. 6–3).[24] Mutations in A or B transferase genes can result in weak expression (subgroup phenotypes) or in nonfunctional O alleles. A and B subgroups result from a large variety of mutations that cause reduced activity of the glycosyltransferase. To date, DNA studies reveal the presence of 41 different A subgroup alleles and 18 B subgroup alleles in various populations.[28] The less common B(A) phenotype results from B-transferase-catalyzed addition of small amounts of A antigen on RBCs that is only detected with highly potent anti-A monoclonal reagents. (Individuals have anti-A in their serum). In cisAB phenotypes, A and B are inherited together from a single locus. Both of these phenotypes, B(A) and cisAB, result from variant glycosyltransferases that, at critical substrate selective positions, have a combination of A- and B-specific residues. For example, in the cisAB shown (Fig. 6–4), the first substitution is identical to that described for the A_2 transferase (Leu156), and the second is that found in the B transferase (Ala268).[29] Five different cisAB and five B(A) backgrounds have now been reported.[28]

Nonfunctional O transferases

The group O phenotype results from any mutation in an A or B transferase gene that causes loss of glycosyltransferase activity and a nonfunctional enzyme. Consequently, there are numerous group O genetic backgrounds. The most common group O (designated O^1 or O_{01}) results from a single nucleotide deletion early in the gene near the N terminus. This allele is referred to as 261delG. The deletion causes a frameshift and a truncated product with no enzyme activity that probably does not reach the Golgi membrane (see Fig. 6–3). Another common O allele (designated O^{1var} or O_{02}) has the same 261delG with nine additional point mutations. Alleles with 261delG are referred to as "deletion phenotypes" to distinguish them from O alleles that result from point mutations or splice site mutations. This distinction has become important with the finding that some "nondeletion" O alleles may retain low levels of glycosyltransferase activity and are often associated with ABO typing discrepancies.[30–32] Although approximately 61 different O alleles have been reported, the two O alleles, O^1 and O^{1var}, are common in all populations examined.[33]

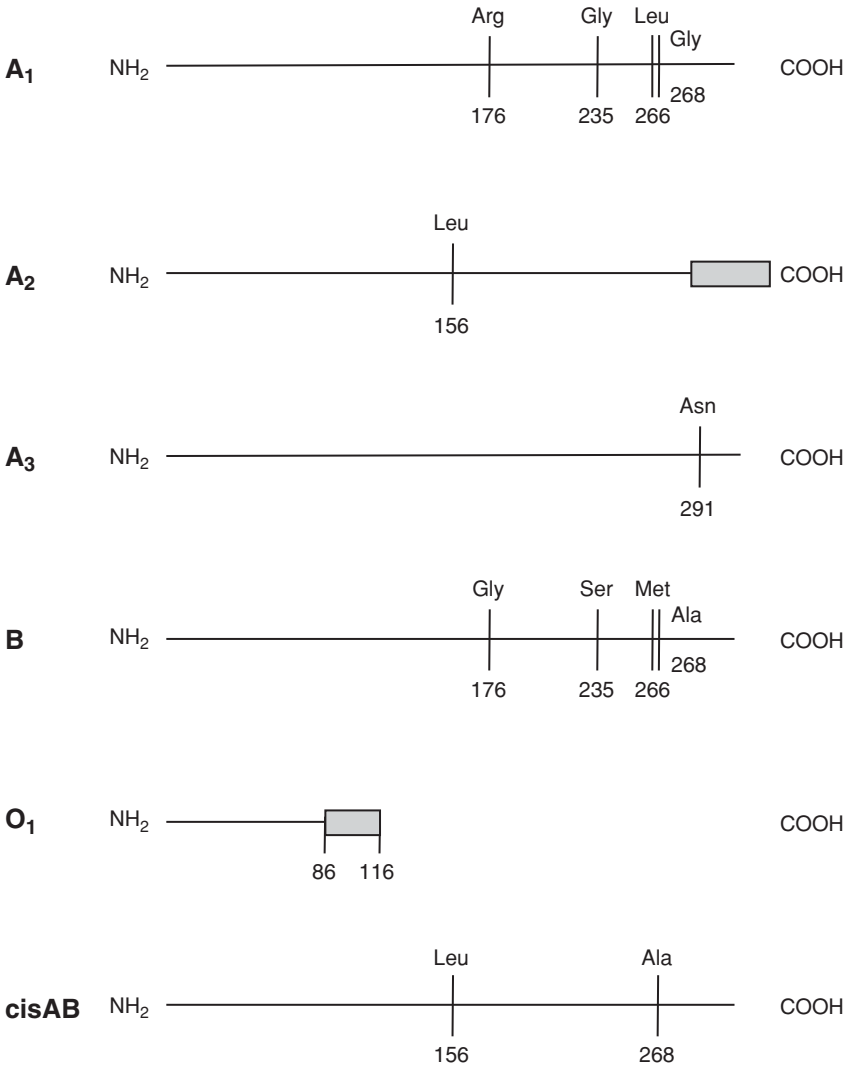

Figure 6–4 Representation of the amino acid sequence differences in the ABO glycosyltransferases. The grey boxes on the A_2 and O_1 glycosyltransferases indicate the altered protein sequence that results from the frameshift gene mutations.

Information regarding the ABO system alleles is maintained and updated on the Blood Group Antigen Mutation Database website (www.ncbi.nlm.nih.gov/projects/mhc/xslcgi.fcgi?cmd=bgmut/home), and can also be found in an issue of *Transfusion Medicine* that is dedicated to the ABO system.[34]

DNA genotyping

A polymerase chain reaction restriction fragment length polymorphism assay can be used to discriminate the common ABO genotypes.[35] This assay will not correctly assign subgroups of A (other than A_2) or subgroups of B, B(A), or cisAB phenotypes, and gene sequencing is often required. Determination of the ABO type with DNA-based approaches is complicated by the number of different subgroup and variant alleles present in populations. Serologic methods also have limitations when testing RBCs from ABO subgroups, but the hope would be that DNA genotyping would be a superior methodology. The observation that the same genotype can give rise to different phenotypes even within families, possibly due to genetic or somatic recombination events,[32] has added an additional layer of complexity to the ABO system. Although uncommon, these samples present challenges for development of DNA-based testing methods for ABO.

H (FUT1) and Secretor *(FUT2)* Genes

The biosynthesis of H antigen found on RBCs and epidermis and that found in secretions involves two different α1,2-fucosyltransferase enzymes encoded by two closely linked genes on chromosome 19q13.3,[36] *FUT1* and *FUT2*. These genes are also referred to as the *H* gene and the *Se* (secretor) gene. Both encode enzymes that add an H-specific fucose sugar to a precursor oligosaccharide core structure, but they act on different precursor structures. Four different core structures, all tetrasaccharides (four sugars) with terminal galactose residues, are found in human cells, and these core structures differ among tissues.[5] Type 1 precursors are found in the acinar cells of salivary glands and the epithelial lining of the pulmonary, gastrointestinal, urinary, and reproductive tracts. Type 2 precursors are expressed by RBCs and other tissues.[5] These precursors are identical except for the terminal galactose linkage (see Fig. 6–2). H antigen is synthesized in RBCs when the *H* (*FUT1*) gene-encoded fucosyltransferase attaches a fucose via an α1,2 linkage to the terminal galactose of type 2 precursor chains. H antigen in secretions is synthesized when the *Se* (Secretor, *FUT2*) gene-encoded fucosyltransferase attaches a fucose via an α1,2 linkage to the terminal galactose on type 1 precursor chains in secretory tissues. The A and B glycosyltransferases do not discriminate

type 1 or type 2 chains and add *N*-acetylgalactosamine (A) or galactose (B) sugars to H antigens on both (i.e., in secretions and on RBCs) (see Fig. 6–2).

H (*FUT1*) encodes a 365-amino acid type II transmembrane protein, and *Se* (*FUT2*) encodes either a 332- or a 343-amino acid (there are two potential initiator codons) type II transmembrane protein. These genes are similar to A and B transferases in structure. They share 68% identity in a region of 292 amino acids and are clearly homologous. *H* (*FUT1*) is only 9 kb, and the coding region is contained in a single 1.1-kb exon.[37,38]

Homozygosity for defective *Se (FUT2)* is responsible for the nonsecretor (sese) phenotype, which has an incidence of approximately 20%. Numerous mutations cause loss of enzyme activity,[39] and these differ among populations. In white persons, a nonsense mutation at nucleotide G428A (se428) is found, whereas a mutation at se571 is common in Asians, and se849 is often found in Taiwanese. In addition, a normally functioning variant, designated Se^1, and a variant with reduced enzyme activity, *Se(W)*, are found in Asians. (The reduced activity of the *Se(W)* fucosyltransferase is responsible for the rare Le(a+b+) phenotype in Asians).

The majority of nonsecretors have functional *H (FUT1)* with synthesis of H antigen on RBCs. The exceptions, who are homozygous for null alleles at both *H (FUT1)* and *Se (FUT2)* loci, have the rare Bombay phenotype. They lack H antigen both in secretions and on RBCs; therefore, they make potent anti-H and must be transfused with RBCs from other Bombay people. In contrast, para-Bombay individuals are homozygous for null alleles at *H (FUT1)* but have at least one functional *Se (FUT2)* allele; they lack H antigen on their RBCs, but have H antigen in secretions (Table 6–2).[5] Those with a para-Bombay phenotype who are nonsecretors have clinically significant anti-H in their serum. More than 20 different mutations in *H (FUT1)* have been associated with Bombay and para-Bombay phenotypes (summarized by Costache and associates[40]).

Expression

ABO antigens are not fully developed at birth. Cord and infant RBCs have linear oligosaccharide structures with single termini to which the A, B, and H sugars can be added. Not until a person is approximately age 2 to 4 do complex branching oligosaccharide structures appear on the RBCs, which create additional termini. The antigens are then fully developed (and can accurately be tested for A_1 status) and remain fairly constant throughout life.[41–43] ABO-related hemolytic disease of the newborn (ABO-HDN) is usually mild because of the weaker RBC expression of A and B antigens and also because tissue expression provides additional antigen targets for maternal antibodies. Tissue expression of the ABO antigens varies during fetal development, but they are expressed on endothelial and epithelial cells of most organs and RBCs in 5- to 6-week-old embryos.[44]

A, B, and H antigens may be detected on lymphocytes of people with a secretor *(Se)* gene as a result of adsorption from the plasma as glycolipids. In contrast, platelets contain A-, B-, and H-transferases, making A, B, and H antigens intrinsic on platelet glycoproteins.[45]

Evolution

The ABH antigens appear earlier on epithelial cells than on blood cells,[46] so they may have or may have had functions in early development. ABO antigens are present on the RBCs of nonhuman primates—chimpanzee, gorilla, orangutan, gibbon, baboon, and several species of Old and New World monkeys.[47] Therefore, the ABO polymorphism has been maintained from species to species for more than 37 million years,[48] suggesting that there must be some importance to maintaining variation in ABO types. Primate studies reveal that the oldest common ancestral gene is A and that B alleles have arisen from the ancestral A alleles on at least three independent occasions.[49] However, the nonfunctional O allele has become one of the most common alleles and is even fixed in some South American populations. Nonfunctional or null alleles are expected to remain rare, unless they confer a selective advantage. Why the null allele evolved can only be speculated upon at present, but the presence in group O individuals of natural antibodies against A and B determinants may have offered important protection against bacteria and parasites[49] or even smallpox.[50]

Antibodies

Anti-A and anti-B are found in the sera of individuals who lack the corresponding antigens. They are produced in response to environmental stimulants, such as bacteria, and have therefore been termed *natural antibodies.*[51–53] Antibody production begins after birth, reaching a peak at age 5 to 10 and declining with increasing age. The antibodies formed to carbohydrate antigens are mostly immunoglobulin M (IgM). IgM antibodies activate complement, which, in conjunction with the high density of ABO antigen sites on RBCs, is responsible for the severe, life-threatening transfusion reactions that may be caused by ABO-incompatible transfusions.

Table 6–2 **Comparison of H Antigen in Bombay, Para-Bombay, and Normal Phenotypes**

	H Antigen			
Phenotype	**Blood Cells**	**Secretion**	**Predicted Genotype**	**Antibody**
Common				
Secretor	H+	Yes	*HH, Hh, SeSe, Sese*	
Nonsecretor	H+	No	*HH, Hh, sese*	
H-Deficient				
Bombay	H-	No	*hh, sese*	Anti-H
Para-Bombay	H weak	No	*(H), sese*	Anti-H
Para-Bombay	H weak	Yes	*(H), SeSe, Sese*	Anti-HI

Hemolytic disease of the newborn caused by ABO antibodies is usually mild, for the following reasons: placental transfer is limited to the fraction of IgG anti-A and anti-B found in maternal serum, fetal ABO antigens are not fully developed,[54] and ABO tissue antigens provide additional targets for the antibodies. ABO-HDN is most often seen in non-group O infants of group O mothers, because anti-A, anti-B, and anti-A,B of group O mothers often has a significant IgG component.

Potent anti-H (along with anti-A and anti-B) found in O_h (Bombay) or para-Bombay nonsecretors destroys transfused RBCs of any ABO group, so these individuals must be transfused only with blood of the Bombay phenotype.[55] In contrast, anti-H in non-Bombay individuals is usually IgM and clinically insignificant. Anti-IH is not uncommonly found in patient sera and is usually IgM; compatible blood is easily found among donors of identical ABO type.[15,56]

Enzyme-Converted O Cells (ECO)

Blood group O is considered the *universal donor* because it can be transfused to patients of all ABO types. Therefore, enzymes that remove terminal carbohydrates from the nonreducing end of carbohydrate chains could be used to remove terminal A and B sugars to convert the blood supply to all universal group O units. An enzyme from coffee beans, α-galactosidase, has been the most successful at removing galactose to convert blood group B to group O. RBCs treated in this manner have normal survival when transfused to group B, A, or O recipients.[57] Removal of *N*-acetylgalactosamine to convert group A to group O has been much more problematic, owing to the inaccessibility of the carbohydrates on internal branching chains, especially those found on A_1 cells. The procedures required to convert B to O, which include exposure to low pH followed by numerous washings, make them impractical for general use. This is an active area of research and alternative enzymes and improved methodologies are under investigation.[58,59]

THE LEWIS SYSTEM (ISBT SYSTEM 007)

History

The Lewis system, first reported in 1946 by Mourant,[60] was named after the first patient to make the antibody. What was thought at the time to be the antithetical antigen was found in 1948, and the designations Le^a and Le^b were applied at a later time.[19] We now know that these antigens are not antithetical, because they are not products of alternative forms of a single gene. Rather, they result from the sequential action of two fucosyltransferases encoded at independent loci (*LE-FUT3* and *Se-FUT2*).

Antigens

Lewis antigens, unlike antigens of all other blood group systems except Chido-Rodgers, are not intrinsic to the RBC but are synthesized in the intestinal epithelial cells. Lewis antigens circulate in plasma while bound to glycosphingolipids and are passively adsorbed onto RBCs.[61,62]

There are four Lewis phenotypes—Le(a+b−), Le(a−b+), Le(a−b−), and the rare Le(a+b+). African Americans have a higher incidence of the Le(a−b−) phenotype, and Le(a+b+) is very rare in white persons and African Americans but not uncommon in Asians (Table 6–3).

Le^a and Le^b are synthesized in a stepwise manner by two transferase enzymes that add fucose residues only to type 1 chains, which are found in secretions but not in RBCs (see Fig. 6–2). The nature and substrate specificity of the enzymes have been elucidated only recently. The α1,4-fucosyltransferase encoded by *LE (FUT3)* catalyzes the addition of a fucose to carbon 4 of the subterminal *N*-acetylglucosamine (GlcNAc) residue of the type 1 precursor chains, creating the Le^a structure (see Fig. 6–2). (Note that this transferase cannot act similarly on the type 2 chains found on RBCs, because they already have Ga1 on carbon 4 of the subterminal GlcNAc, which blocks the acceptor site; this fact explains why the Lewis antigens are not synthesized in RBCs.)

Table 6–3 **Lewis Blood Group Phenotypes and Incidence**

	Incidence (%)		
Phenotype	**White**	**African**	**Asian**
Le(a−b+)	72	55	72
Le(a+b−)	22	23	22
Le(a−b−)	6	22	6
Le(a+b+)	Rare	Rare	3

The Le^a structure remains unchanged, resulting in the Le(a+b−) phenotype, unless the individual is a secretor *(Se-FUT2)*. In the presence of the α1,2-fucosyltransferase encoded by the secretor locus, the Le^a structure is converted to Le^b by the addition of a fucose residue to carbon 2 of the terminal galactose residue on the same chain. Le^b antigen is synthesized at the expense of Le^a antigen, resulting in the Le (a−b+) phenotype. This finding explains early observations that individuals with RBCs that typed as Le(b+) were secretors of ABH substance, those with Le(a+) RBCs were nonsecretors, and individuals with Le(a−b−) RBCs could be either secretors or nonsecretors of ABH. Ninety percent of white persons inherit normal *LE (FUT3),* and 80% carry a functional *Se (FUT2),* accounting for the prevalence of the Le(a−b+) phenotype in the white population (see Table 6–3).[5,50]

Le(a−b−) arises from homozygous defects in *LE (FUT3),* regardless of the *Se (FUT2)*. Le(a+b+) individuals have weak expression of both Le^a and Le^b and are sometimes called *partial secretors*. They have significantly reduced α1,2-fucosyltransferase activity, and this uncommon phenotype is principally found in Taiwanese.

Genes

The gene responsible for Lewis carbohydrates, *LE (FUT3),* located on chromosome 19 (19p13.3), encodes a 361-amino acid, type II membrane-bound enzyme.[63] It is one of the series of genes located on chromosome 19 that encode fucosyltransferases. Chromosome 19 is also the location for both the secretor gene *Se (FUT2)*—which not only determines ABH secretor status but also interacts with *LE* (*FUT3*) to synthesize Le^b antigens—and the *H* gene (*FUT1*)—which is responsible for H antigen on RBCs.

Le(a−b+) individuals have a least one functional *LE (FUT3)* and *Se (FUT2),* and are secretors of ABH antigens. Le(a+b−) individuals have at least one functional *LE (FUT3),* but this phenotype identifies the 20% of individuals with defective *Se (FUT2)* (see discussion of the ABO system). Le(a+b+), found in relatively high prevalence in Taiwan, results from inheritance of *Se(w),* which encodes an amino acid change in the catalytic

domain resulting in reduced activity of the enzyme encoded by *Se (FUT2)*. Le(a−b−) individuals have point mutations in the *LE (FUT3)* gene *(le/le)*. Many different defective alleles (*le*^{1}-*le*^{6}) have been reported, and mutations at nucleotides 508, 1067, and 202 severely reduce or inactivate the fucosyltransferase.[39] A mutation at nucleotide 59 results in an amino acid change in the transmembrane domain, which does not affect the enzyme activity but may affect the Golgi localization. This mutation is responsible for the paradoxical Le(a−b−) RBC phenotype in people with Lewis antigens in their saliva.[64]

Expression

Lewis antigens are not expressed on cord RBCs. Lewis antigen levels on RBCs are often diminished during pregnancy, possibly due to pregnancy-associated changes in plasma lipoproteins.[65] Lewis antigens are also found on lymphocytes and platelets (secondarily adsorbed from the plasma); on other tissues, including pancreas, stomach, intestine, skeletal muscle, renal cortex, and adrenal glands; and in soluble form in saliva as glycoproteins. Lewis antigens may be of some consequence in renal allografts. Graft survival has been reported to be reduced in patients who lack Lewis antigens, but this issue is controversial.[18] The Le^{b} antigen may be a receptor for *Helicobacter pylori,* a feature that could explain the association of gastric ulcers and secretor status.[66,67]

Antibodies

Lewis antibodies are primarily IgM and are usually not clinically significant. Lewis antibodies often complicate antibody identification when multiple antibodies are present, but they are easy to inhibit with saliva (made isotonic) from secretors or with commercially prepared Lewis substance. Lewis antibodies occur in the sera of Le(a−b−) persons and may be naturally occurring.[15]

Rare hemolytic transfusion reactions, due to transfusion of Le(a+) RBCs to recipients with anti-Le^{a}, have been reported.[68] Because Le(a−) RBCs are found in almost 80% of donors, it is easy to select Le(a−) RBCs for transfusion to recipients with anti-Le^{a} when the antibody is reactive at 37°C.[69] Because Lewis antigens are not intrinsic to the RBC membrane and are present in plasma, selection of Le(b−) RBCs is unnecessary for recipients with anti-Le^{b}, because Lewis antigens in donor plasma readily neutralize Lewis antibodies in transfusion recipients.[61]

The intimate relationship between Lewis and ABH antigens is revealed by antibodies such as anti-Le^{bH}, which reacts best with O Le(b+) cells. Crossmatching ABO-identical RBCs (rather than O) usually provides compatible blood. Anti-Le^{bA} reacts best with A Le(b+) cells. These antibodies are IgM and not clinically significant.

Anti-Le^{a} and anti-Le^{b} are not known to cause HDN, because they are usually IgM, and because fetal RBCs type as Le(a−b−).[15]

THE Ii BLOOD GROUP COLLECTION (ISBT COLLECTION 207)

History

In 1956, Wiener and colleagues[70] described the I antigen after making an intense study of a particularly severe case of hemolysis, or cold agglutinin disease, due to anti-I. They used the symbol I to emphasize the high degree of *I*ndividuality of RBCs failing to react with the patient's serum at room temperature. Because the patient's serum was only weakly reactive in vitro with bovine RBCs, she was transfused with a small volume of bovine RBCs, but an anaphylactic-type reaction discouraged Wiener and colleagues[70] from further attempts to transfuse bovine RBCs.

Antigens

I and i antigens on RBCs are subterminal portions of the same carbohydrate chains that carry ABH antigens.[18] I and i are not allelic; rather, they differ in their branching structure. The i antigen, found predominantly on fetal and infant RBCs, is characterized by disaccharide units (Gal-GlcNAc) linked in a straight chain.[71] During the first 2 years of life, many of these linear chains are modified into branched chains,[41] resulting in the appearance of I antigens found on adult RBCs. I specificity develops at the expense of i antigens when the branched structures appear.

Gene

The gene responsible for I antigen synthesis on RBCs and in tissues, called *IGnT* (GCNT2), consists of three exons and is located on chromosome 6p24.[72] The gene encodes β1,6-*N*-acetylglucosaminyltransferase, a type II membrane protein similar in structure to other glycosyltransferases.[73] This enzyme is responsible for the branching synthesis of I antigen and so is probably developmentally regulated. The gene has three forms of exon 1 that are differentially spliced to give three transcripts—IGnTA, IGnTB, or IGnTC—each responsible for synthesis of I antigen in various tissues (Fig. 6–5).[72,74,75] For example, I antigen on RBCs is encoded by IGnTC, and expression of I antigen in lens epithelium is encoded by IGnTB.

The I-negative phenotype (adult i) in Taiwanese and in Japanese is associated with three different mutant alleles; all have a Gly348Glu change encoded in exon 3, with or without Arg383His (exon 3) or Gly334Arg (exon 2), or a large gene deletion encompassing exons 1B, 1C, and exons 2 and 3.[72] In whites, an Ala169Thr change, with or without Arg228Gln, encoded by IGnTC exon 1C causes adult i. In Japanese, the adult i phenotype has been associated with congenital cataracts,[76,77] but this has not been observed in whites.[78] The different genetic backgrounds explains these observations, because the white mutation in exon 1C affects RBC expression of the I antigen, but normal I antigen is expressed in lens epithelium. In contrast, mutations in exon 3 of *IGnT* found in Taiwanese and Japanese persons result in lack of transferase

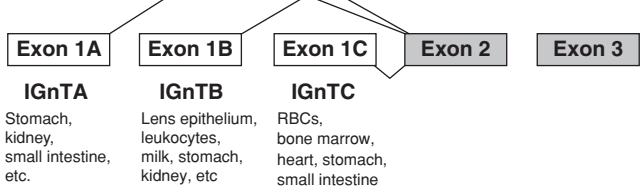

Figure 6–5 Representation of the *IGnT* gene. Altenative splicing generates three different transcripts responsible for I antigen synthesis in the tissues indicated.

activity on RBCs and lens epithelium. The human *IGnT* gene appears to have some role in maintaining lens transparency (reviewed in Reid[79]).

Expression

Adult RBCs express predominantly I antigens and little or no i antigen, whereas newborn infant RBCs have strong expression of i antigens and small amounts of I antigen.[80] Adult RBCs vary in the amount of I antigen. I and i can also be found on lymphocytes and platelets. The I and i antigens are referred to by some as *histo-blood group antigens* because, like ABH antigens, they are not restricted to RBCs but are found on most cells and in various body fluids.[18] Many conditions that result in stress hematopoiesis result in altered I and i antigen expression; typically, I expression is weakened but i expression is enhanced. For example, decreased expression of I antigen with concomitant increase in i antigen expression are associated with leukemia, Tk polyagglutination, thalassemia, sickle cell disease, hereditary erythroblastic multinuclearity with positive acidified serum, congenital hypoplastic anemia, myeloblastic erythropoiesis, and sideroblastic erythropoiesis.[81]

Antibodies

The sera of all individuals contain anti-I as a common autoantibody that is reactive at or below room temperature and is usually benign. These autoantibodies are commonly referred to as *cold agglutinins*. If the autoantibody is reactive at room temperature, problems in compatibility testing may result, but prewarming components and testing at 37°C easily circumvents them.[82] Even in patients undergoing hypothermia during surgical procedures, there are no reports of anti-I causing RBC destruction. Alloantibody to I made by the rare i adult phenotype is clinically significant and causes destruction of transfused I+ RBCs.

In contrast, cold agglutinin disease is characterized by high titers of monoclonal anti-I antibodies, which cause in vivo hemolysis and hemolytic anemia. These pathologic autoantibodies often react at 30°C in albumin and can fix complement.[83] The autologous circulating RBCs of a patient with cold agglutinin disease are often strongly coated with complement component C3d, making them relatively resistant to destruction. In contrast, when donor RBCs are transfused to a patient with cold agglutinin disease, they may be rapidly destroyed by circulating antibody. If transfusion cannot be avoided, donor RBCs should be transfused through a blood warmer.[15]

The titer and thermal range of anti-I are often increased after infection with *Mycoplasma pneumoniae.*[16] Approximately 50% of patients with infectious mononucleosis may have transient anti-i in their sera, but less than 1% have hemolysis.[84] Transient autoantibody to i can occur in patients with lymphoproliferative disorders (e.g., Hodgkin's disease).

THE P SYSTEM (ISBT SYSTEM 003) AND GLOB COLLECTION (ISBT COLLECTION 209)

History

The P blood group system was first discovered by Landsteiner and Levine[85] in 1927 after they injected rabbits with human RBCs. The first antigen discovered in this system appeared to be present on all human RBCs. It was named the P antigen because this was the first letter after M, N, and O, which had already been used. This antigen, present in 79% of white people, was renamed P_1; according to current ISBT terminology, however, the name is now written as P1, whereas P_1 denotes the P1+ phenotype.[4,19] This chapter uses the more familiar P_1 terminology. Other related antigens P, P^k, and LKE have been assigned to the GLOB collection because, although they are related biochemically to the P_1 antigen, their genetic association is still unclear.

Antigens

The P_1, P, and P^k blood group antigens are defined by sugars added to precursor glycosphingolipids and are not found on glycoproteins. Biosynthesis occurs by the sequential addition of monosaccharides to a precursor substrate catalyzed by glycosyltransferases. Two pathways are involved in the production of these antigens from a common precursor, galactose β1,4-glucose-ceramide, also called *lactosylceramide* (Fig. 6–6). In one pathway, lactosylceramide is converted to P^k (also called CD77), an antigen of very high incidence that is the precursor structure for synthesis of P. P is produced by the action of a second enzyme, and P antigen is found on all RBCs except the rare p and P^k phenotypes.

The P antigen is a cellular receptor for the B19 parvovirus, which causes erythema infectosum (fifth disease), a common childhood illness, and occasionally can cause more severe disorders of erythropoiesis. The virus causes both transient aplastic crises in patients with underlying hemolysis and anemia in immunocompromised patients.[86] Individuals with the p phenotype lack both P and P^k and are naturally resistant to parvovirus B19 infection. P^k (CD77) is present on epithelial cells and immature B cells in the germinal center and is a receptor molecule for Shiga-like toxins from *Escherichia coli* 0157.[87] LKE antigen is formed when two additional carbohydrate residues (galactose and sialic acid) are added to P (see Fig. 6–6).

In the second pathway, lactosylceramide is converted to P_1 antigen. The biochemical pathway is not completely established, and whether the same α1,4-galactosyltransferase gene is responsible for synthesis of both P^k and P_1 antigens is debated. P_1 antigen is a receptor for uropathogenic strains of *E. coli,* and it has been suggested that P_1 on urinary tract tissue allows the bacteria to bind to and ascend the urinary tract more easily.[50]

The RBC phenotypes that carry various combinations of these antigens are shown in Table 6–4. The nomenclature can be confusing, but five phenotypes, depending on the presence or absence of the three antigens—P_1, P, and P^k—are known. The presence of all three antigens results in the P_1 phenotype. The absence of P_1 results in the P_2 phenotype. P_1 and P_2 phenotypes are common. Among white persons, 21% are P_1 negative, but the incidence of P_1 negative people is greater in Southeast Asian populations; 80% of Cambodians and Vietnamese are P_1 negative. The absence of all three antigens is associated with the "null" p phenotype.

Genes

Two genes code for the P^K and P synthesizing enzymes, 4-α-galactosyltransferase (α4Gal-T, Gb3)[88] and 3-β-*N*-acetylgalactosaminyltransferase (β3GalNAcT, Gb4)[89] (see Fig. 6–6).

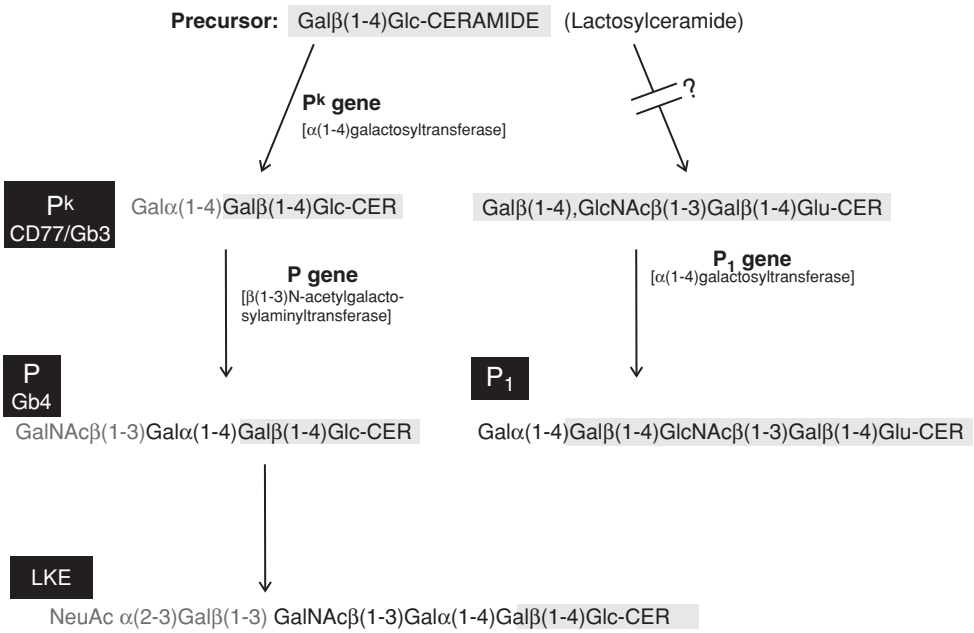

Figure 6–6 Biosynthesis of the P_1, P^k, P, and LKE antigens. Glu, glucose; CER, ceramide.

Table 6–4 P Blood Group System Phenotypes and Incidence

Phenotypes	Incidence (%) Whites	Incidence (%) African Americans	Antigens
P_1	79	94	P_1, P, P^{k*}
P_2	21	6	P, P^{k*}
P_1^k	Very rare	Very rare	P^1, P^k
P_2^k	Very rare	Very rare	P^k
p	Very rare	Very rare	None

*P^k is difficult to detect on these cells because it is converted to P.

The p "null" phenotype is due to alterations and mutations in the α*4Gal-T* transferase gene, which acts on the precursor lactosylceramide.[90] Eleven different P^k-null (p phenotype) alleles have been reported from donors with different geographic backgrounds (summarized in Hellberg et al.[91]). Mutations in the gene for β3GalNAcT, Gb4 lead to the P_1^k and P_2^k phenotypes[92] (see Fig. 6–6). The genetic background for the P_1 antigen remains unknown, and why the P_2 and p phenotypes are associated with the absence of P_1 antigen has not been established.

Expression

P_1 antigen is considerably weaker in children than in adults, and its expression does not reach adult level until age 7. However, P_1 antigen is more strongly expressed on fetal RBCs than on neonatal RBCs, and P_1 expression weakens as the fetus ages. RBCs from different people show variation in the strength of the P_1 antigen, which can be seen during analysis of panel results in the identification of anti-P_1. P_1 and P are also expressed on lymphocytes, granulocytes, and monocytes.[18]

P_1 antigens are expressed in a wide variety of organisms, including bacteria, nematodes, earthworms, liver flukes, pigeons, and tapeworms.[18]

Antibodies

P_1-negative individuals frequently produce anti-P_1. This cold-reactive IgM antibody does not cross the placenta and has rarely been reported to cause hemolysis in vivo.[93] Like Lewis antibodies, anti-P_1 can often complicate antibody identification when multiple antibodies are present. However, anti-P_1 antibodies are easily neutralized with commercially prepared P_1 substance. Hydatid cyst fluid, *Echinococcus* cyst fluid, or pigeon egg white may be used. Anti-P^k is also neutralized by these substances.

Persons with the very rare p phenotype lack P_1, P, and P^k antigens and may produce anti-P,P_1,P^k (anti-Tj^a), a potent hemolytic IgM antibody that can cause immediate hemolytic transfusion reactions.[15,19] In women with the p, P_1^k, or P_2^k phenotypes, cytotoxic IgM and IgG3 antibodies directed against P antigens, P^k antigens, or both, are associated with a higher than normal rate of spontaneous abortions.[18,94]

Autoantibody to P, the Donath-Landsteiner autoantibody, is found in patients with paroxysmal cold hemoglobinuria and in some patients with acquired immune hemolytic anemia.[95] The autoantibody, complement-fixing IgG, is a biphasic hemolysin that binds to RBCs in the cold and then hemolyzes them when warmed. Thus, the patient's serum causes hemolysis of RBCs that have been first incubated

in melting ice and then incubated at 37°C.[96] This antibody should be considered when the patient has hemoglobinuria and C3 alone is present on the RBCs. Transfusion is seldom required in paroxysmal cold hemoglobinuria, because the anemia is usually transient. P-negative blood is rare, and P-positive blood has been used successfully for transfusion in patients with severe anemia.[15]

SUMMARY

Despite the clinical relevance, especially of the ABO blood groups, the physiologic function of the carbohydrate antigens is unclear. The fact that some microbes and parasites use the carbohydrate blood group determinants as receptors certainly may contribute to their variation but does not shed light on their function. Specific interactions between cells might involve the blood group portions of cell surface glycoconjugates. Certainly, the carbohydrate structures on RBCs are important to impart the net negative charge on the membrane, keeping RBCs from adhering to one another and to the extracellular matrix. However, at present, the specific function of these carbohydrate molecules is unknown.

Chapter 7

Rh, Kell, Duffy, and Kidd Antigens and Antibodies

Connie M. Westhoff • Marion E. Reid

This chapter summarizes four clinically significant blood group systems that are defined by protein polymorphisms. The proteins that carry these blood group antigens were difficult to isolate because they are integral membrane proteins present as minor components of the total red blood cell (RBC) protein. Biochemical techniques developed in the 1970s and 1980s enabled their purification and partial amino acid sequencing. In the 1990s, the protein sequence data were used to construct nucleic acid probes for amplification and screening of bone marrow cDNA libraries to isolate the genes. In the past decade, there has been a considerable increase in the amount of information about these blood group antigens; principally, the development and use of the polymerase chain reaction (PCR) has resulted in the rapid elucidation of the molecular basis for the antigens and phenotypes. In addition, the structure and function of these membrane proteins is an active area of investigation.

Rh BLOOD GROUP SYSTEM

History

The Rh system is second only to the ABO system in importance in transfusion medicine. Rh antigens, especially D, are highly immunogenic and can cause hemolytic disease of the newborn (HDN) and severe transfusion reactions. HDN was first described by a French midwife in 1609 in a set of twins, of whom one was hydropic and stillborn, and the other was jaundiced and died of kernicterus.[1,2] In 1939, Levine and Stetson[3] described a woman who delivered a stillborn fetus and suffered a severe hemolytic reaction when transfused with blood from her husband. Her serum agglutinated the RBCs of her husband and 80 of 104 ABO-compatible donors. Subsequently, in 1941, Levine and colleagues[4] correctly concluded that the mother had been immunized by the fetus, which carried an antigen inherited from the father, and suggested that the cause of the *erythroblastosis fetalis* was maternal antibody in the fetal circulation. Attempts to immunize rabbits against this new antigen were not successful.[1] Levine and colleagues did not name the antigen.[5]

Meanwhile, Landsteiner and Wiener, in an effort to discover additional blood groups, injected rabbits and guinea pigs with rhesus monkey RBCs. The antiserum agglutinated not only rhesus cells but also the RBCs of 85% of a group of white subjects from New York, whom the researchers called *Rh positive;* the remaining 15% were *Rh negative.*[1] Because the *anti-Rhesus* appeared to have reactivity indistinguishable from the maternal antibody reported by Levine and Stetson, the antigen responsible for HDN was named *Rh.* Later it was realized that the rabbit antiserum was not recognizing the same antigen but was detecting an antigen found in greater amounts on Rh-positive than on Rh-negative RBCs.[6] This antigen was named LW for Landsteiner and Wiener,[1] and the original human specificity became known as anti-D.

As early as 1941, it was obvious that Rh was not a simple single antigen system. Fisher named the C and c antigens (A and B had been used for ABO) on the basis of the reactivity of two antibodies that recognized antithetical antigens, and used the next letters of the alphabet, D and E, to define antigens recognized by two additional antibodies.[1] Anti-e, which recognized the e antigen, was identified in 1945.[7]

Nomenclature

The Rh system has long been acknowledged as one of the most complex blood group systems because of its large number of antigens (45) and the heterogeneity of its antibodies. The introduction of two different Rh nomenclatures reflected the differences in opinion concerning the number of genes that encoded these antigens. The Fisher-Race nomenclature was based on the premise that three closely linked genes — C/c, E/e, and D — were responsible, whereas the Wiener nomenclature (Rh-Hr) was based on the belief that a single gene encoded one *agglutinogen* that carried several blood group factors.

Even though neither theory was correct (there are two genes, *RHD* and *RHCE*, correctly proposed by Tippett[8]), the Fisher-Race designation (CDE) for haplotypes is often preferred for written communication, and a modified version of Wiener's nomenclature (the original form is nearly obsolete) is preferred for spoken communication (Table 7–1). A capital "R" indicates that D is present, and a lowercase "r" (or "little r") indicates that it is not. The C or c and E or e Rh antigens carried with D are represented by subscripts: 1 for Ce (R_1), 2 for cE (R_2), 0 for ce (R_0), and Z for CE (R_z). The CcEe antigens present without D (r) are represented by superscript symbols: "prime" for Ce (r'), "double-prime" for cE (r") and "y" for CE (r^y) (see Table 7–1). The "R" versus "r" terminology allows one to convey the common Rh antigens present on one chromosome in a single term (a phenotype). Dashes are used to represent missing antigens of the rare deletion (or CE-depleted) phenotypes; for example, D– – (referred to as D dash, dash) lacks C/c and E/e antigens.

In 1962, Rosenfield and associates[9] introduced numerical designations for the Rh antigens to more accurately represent

Table 7–1 **Nomenclature and Prevalence for Rh Haplotypes**

Haplotype Based on Antigens Present	Shorthand for Haplotype	Prevalence (%)		
		White	African American	Asian
DCe	R_1	42	17	70
DcE	R_2	14	11	21
Dce	R_0	4	44	3
DCE	R_z	<0.01	<0.01	1
ce	r	37	26	3
Ce	r′	2	2	2
cE	r″	1	<0.01	<0.01
CE	r^y	<0.01	<0.01	<0.01

the serologic data, to be free of genetic interpretation, and to be more compatible for computer use (Table 7–2). However, this numerical nomenclature, with a few exceptions (Rh17, Rh32, Rh33), is not widely used in the clinical laboratory.

Terminology

Current Rh terminology distinguishes the genes and the proteins from the antigens, which are referred to by the letter designations, D, C, c, E, e, and so on. To indicate the RH genes, capital letters, with or without italics, are used (i.e., RHD, RHCE, and RHAG). The different alleles of the *RHCE* gene are designated *RHce, RHCe, RHcE,* according to which antigens they encode. In contrast, the proteins are designated RhD, RhCE (or according to the specific antigens they carry, Rhce, RhCe, or RhcE), and RhAG. RH haplotypes are designated Dce, DCe, DcE, etc., or ce, Ce, cE when referring to a specific CE haplotype.

Proteins

Despite the clinical importance of the Rh blood groups, the RBC membrane proteins that carry them were identified only in the late 1980s.[10,11] The extremely hydrophobic nature of these multipass transmembrane proteins made the biochemical isolation difficult and limited progress in their characterization until the genes were cloned.

The Rh proteins, designated RhD and RhCE, are 417-amino acid, nonglycosylated proteins; one carries the D antigen, and the other carries various combinations of the CE antigens (ce, cE, Ce, or CE).[12–14] RhD differs from RhCE by 32 to 35 amino acids (depending on which form of RhCE is present), and both are predicted to span the membrane 12 times. They migrate in SDS-PAGE (sodium dodecyl sulfate–polyacrylamide gel electrophoresis) gels with an approximate molecular weight ratio (M_r) of 30,000 to 32,000, and hence are sometimes referred to as the *Rh30 proteins.* They are covalently linked to fatty acids (palmitate) in the lipid bilayer.[15]

A 409-amino acid glycosylated protein that coprecipitates with RhD and RhCE proteins and migrates with an approximate M_r of 40,000 to 100,000 is called RhAG (*Rh-a*ssociated *g*lycoprotein) or Rh50 glycoprotein to reflect its apparent molecular weight.[16] RhAG (Rh50) shares 37% amino acid identity with the RhD and RhCE proteins and has the same predicted membrane topology. RhAG is not polymorphic and does not carry Rh antigens. It is important for targeting the RhD and RhCE to the membrane, because mutations in, or lack of expression of, RhAG results in a lack of Rh antigen expression (Rh-null) or a marked reduction of Rh antigen expression (Rh-mod).[17] RhAG has one N-glycan chain that also carries ABO and Ii specificities (Fig. 7–1).

Rh-null and the Rh-Core Complex

Rh-null erythrocytes, which lack expression of Rh antigens, are stomatocytic and spherocytic, and affected individuals have variable degrees of anemia.[18,19] The phenotype is rare, occurring on two different genetic backgrounds; the *regulator* type, caused by mutations in the *RHAG* gene, and the *amorph* type, which maps to the *RH* locus. The amorph Rh-null results from mutations in *RHCE* on a deleted *RHD* background.[20] Regulator RBCs express no Rh and RhAG proteins, whereas amorph type RBCs have no Rh proteins but have reduced (20% of normal) RhAG.

Rh and RhAG proteins are associated in the membrane, possibly as a tetramer consisting of two molecules of each as a core complex,[21] although the precise configuration is not yet known. Evidence that other proteins interact with this Rh-core complex comes from observations that Rh-null RBCs have reduced expression of CD47 (an integrin-associated protein) and of glycophorin B (a sialoglycoprotein that carries S or s and U antigens). Rh-null RBCs also lack LW (ICAM-4), a glycoprotein of approximate M_r 42,000 that belongs to the family of intercellular adhesion molecules. Band 3 (the red cell anion exchanger AE1) may also be associated with the Rh complex.[22] The Rh complex is linked to the membrane skeleton via Rh/RhAG–ankyrin interaction[23] and CD47–protein 4.2 association.[24] Some mutations underlying Rh-null disease involve potential contact sites between RhAG and RhCE/RhD and cytoskeleton ankyrin, which may explain the morphologic defect in these erythrocytes.[23]

Genes

Two genes, designated *RHD* and *RHCE*, encode the Rh proteins. Rh-positive individuals have both genes, whereas most Rh-negative white people have only the *RHCE* gene.[25] The genes are 97% identical. Each gene has 10 exons and is the result of a gene duplication on chromosome 1p34–p36.[26] A comprehensive diagram of the intron–exon structure of *RHD* and *RHCE* can be found in the review by Avent and Reid.[27]

The single gene, *RHAG*, located at chromosome 6p11–p21.1 encodes RhAG. *RHAG* is 47% identical to the *RH* genes and also has 10 exons.[16,28]

ISBT, International Society for Blood Transfusion.

Antigens

As previously described, the major Rh antigens are D, C, c, E, and e. The many other Rh antigens (see Table 7–2) define compound antigens in *cis* (e.g., f (ce), Ce, and CE), low-incidence antigens arising from partial D hybrid proteins (e.g., D^w, Go^a, BARC), high-incidence antigens, and other variant antigens. The molecular bases of most Rh antigens have been determined.

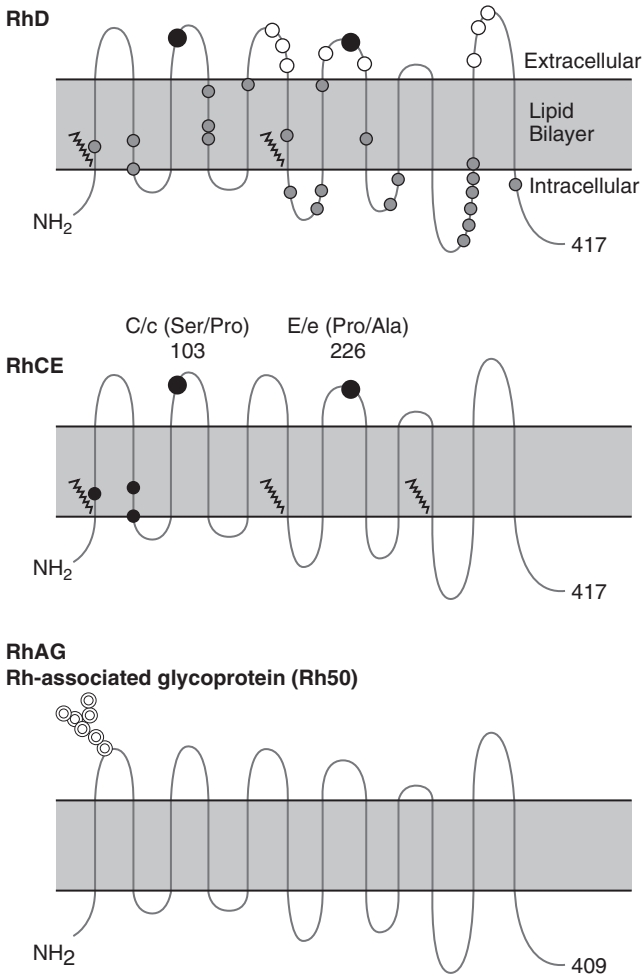

Figure 7–1 Predicted 12-transmembrane domain model of the RhD, RhCE, and RhAG proteins in the red blood cell membrane. The amino acid differences between RhD and RhCE are shown as symbols. The eight extracellular differences between RhD and RhCE are indicated as *open circles*. The *zigzag lines* represent the location of possible palmitoylation sites. Positions 103 and 226 in RhCE that are critical for C/c and E/e expression, respectively, are indicated as *black circles*. The N-glycan on the first extracellular loop of the Rh-associated glycoprotein is indicated by the *branched structure*.

Studies to estimate the number of D, C/c, and E/e antigen sites on RBCs found differences between Rh phenotypes. The number of D antigens ranges from 10,000 on Dce/ce RBCs to 33,000 on DcE/DcE. The number of C, c, and e antigens per RBC varies from 8500 to 85,000.[6] Because C or c and E or e are carried on the same protein, their numbers should be equivalent. The equivalency was not always demonstrated in these studies, reflecting the inherent difficulty in the use of radiolabeled polyclonal antiserum to estimate antigen numbers. Results of tests with monoclonal antibodies to high-incidence Rh antigens suggest that the total number of Rh proteins (RhD and RhCE) per RBC is 100,000 to 200,000. The number of RhAG is also estimated to be 100,000 to 200,000,[29] consistent with predictions that Rh and RhAG may be present in the membrane as a tetramer of two molecules of each.[21]

D Antigen

Rh positive and *Rh negative* refer to the presence and absence, respectively, of the D antigen, which is the most immunogenic of the Rh antigens. The Rh-negative (D-negative) phenotype

occurs in 15% to 17% of white persons but is not common in other ethnic populations. The absence of D in people of European descent is primarily the result of deletion of the entire *RHD* gene and occurred on a Dce (R_0) haplotype because the allele most often carried with the deletion is ce. However, rare D-negative white persons carry an *RHD* gene that is not expressed because of a premature stop codon,[30] a 4-base pair (bp) insertion at the intron 3/exon 4 junction,[31] point mutations, or *RHD/CE* hybrids.[32,33] Most of these are associated with the uncommon Ce (r′) or cE (r′′) haplotypes.

D-negative phenotypes in Asian or African persons, however, are most often caused by inactive or silent *RHD* rather than a complete gene deletion. Asian D-negative individuals occur with a frequency of less than 1%, and most carry mutant *RHD* genes associated with *Ce*,[34] indicating that the gene mutations probably originated on a DCe (R_1) haplotype. Only 3% to 7% of South African black persons are D negative, but 66% of this group have *RHD* genes that contain a 37-bp internal duplication,[35] which results in a premature stop codon. The 37-bp insert *RHD*-pseudogene was also found in 24% of D-negative African Americans. In addition, 15% of the D-negative phenotypes in Africans result from a hybrid *RHD-CE-D*^{s} gene characterized by expression of VS, weak C and e, and no D antigen.[35] Only 18% of D-negative Africans and 54% of D-negative African Americans completely lack *RHD*.

WEAK D (FORMERLY D^u)

An estimated 0.2% to 1% of white persons (and a greater number of African Americans) have reduced expression of the D antigen, which is characterized serologically as failure of the RBCs to agglutinate directly with anti-D typing reagents and requires the use of the indirect antiglobulin test (IAT) for detection. The number of samples classified as *weak D* depends on the characteristics of the typing reagent. These weak D antigens were previously referred to as *D^u*, a term that has been abolished. The molecular basis of weak D expression is heterogeneous. In a large study of samples from Germany,[36] expression of weak D was found to be associated with the presence of point mutations in *RHD*. More than 70% of the samples had a Val270Gly amino acid change, but a total of 16 different mutations were found in the initial study. Since then, a large number of different mutations have been associated with the weak D phenotype (42 to date).[37] Collectively, the weak D phenotypes have amino acid changes predicted to be intracellular or in the transmembrane regions of the RhD protein and not on the outer surface of the RBC,[36] suggesting that the mutations affect the efficiency of insertion and, therefore, the quantity of RhD protein in the membrane but do not affect D epitopes.

The majority of individuals with a weak D phenotype can safely receive D-positive blood and do not make anti-D. However, two weak D types (type 4.2.2 and type 15) have been reported to make anti-D.[38] These weak D individuals would more accurately be classified as partial-D. The serologic differentiation of weak D from partial D is not unequivocal. Importantly, donor center typing procedures must detect and label weak D RBC components as *D-positive*.

A very weak form of D, designated D_{el}, detected by absorption and *el*ution of anti-D, has a high incidence in Hong Kong Chinese and Japanese persons. The D_{el} phenotype most often results from a splice site mutation or deletion that results in the absence of amino acids encoded by exon 9 of *RHD*[39] in Asians or a M295I mutation in whites. These RBCs type as D negative (even when tested using the IAT), and they are usually only recognized if they stimulate production of anti-D in a D-negative recipient.[40,41]

PARTIAL D ANTIGENS (D CATEGORIES OR D MOSAICS)

The D antigen has long been described as a *mosaic* on the basis of the observation that some Rh-positive individuals make alloanti-D when exposed to normal D antigen. It was hypothesized that the RBCs of these individuals lack some part of RhD and that they can produce antibodies to the missing portion. Molecular analysis has shown that this hypothesis is correct, but what was not predicted is that the missing portions of *RHD* are replaced by corresponding portions of *RHCE* (Fig. 7–2).[27,42] Some replacements involve entire exons, and the novel sequence of amino acids generates new antigens (e.g., D^w, BARC, Rh32) (Table 7–3). In addition, several exon rearrangements can give rise to the same partial D category (e.g., D^{VI} can result from type I, II, or III rearrangements; see Fig. 7–2). Other partial D antigens result from multiple amino acid conversions between *RHCE* and *RHD*, and some are the result of single point mutations in *RHD* (D^{VI}, DMH, DFW; see Table 7–3). These point mutations are predicted to be located on an extracellular loop or portion of the RhD protein, in contrast to the weak D antigens already described, which are predicted to have mutations located in cytoplasmic or transmembrane regions. Individuals with partial D antigens can make anti-D and therefore ideally should receive D-negative donor blood. In practice, however, most are typed as D positive and are recognized only after they have made anti-D.

ELEVATED D

Several phenotypes, including D– –, Dc–, and DC^W–, have an elevated expression of D antigen and no, weak, and variant CE antigens, respectively.[6] They are caused by replacement of portions of *RHCE* by *RHD*,[27,42] analogous to the partial D rearrangements already described. The additional *RHD* sequences in *RHCE* along with a normal *RHD* may explain the enhanced D and accounts for the reduced or missing CE antigens. Immunized people with these CE-depleted phenotypes make anti-Rh17.

D EPITOPES EXPRESSED ON RHCE PROTEINS (R_0HAR, ceCF, ceRT)

Some Rhce proteins carry D-specific amino acids that react with some monoclonal anti-D reagents, adding further complexity to D antigen typing. Two examples, R_0^{Har} (D^{HAR}), found in individuals of German ancestry,[43] and Crawford (ceCF, Rh43), found in individuals of African ancestry, deserve attention because of their strong reactivity (3+-4+) with some FDA-licensed monoclonal reagents and lack of reactivity with others (including the weak D test) (Table 7–4). Individuals with R_o^{Har} do not have a *RHD* gene, but exon 5 of the *RHCE* gene is from *RHD* (see Fig. 7–2). Those that carry a Crawford allele, ceCF, also do not have a *RHD* gene, but have a Rhce protein with three amino acid changes, Trp16Cys, Leu245Val, and Gln233Glu. The latter two are D-specific residues responsible for reactivity with a monoclonal anti-D (see Table 7–4 and Fig. 7–2).[44,45] Individuals with R_0^{Har} or Crawford phenotypes make anti-D when stimulated[46] (our unpublished observations), and should be considered Rh negative for transfusion and Rh immune globulin prophylaxis.

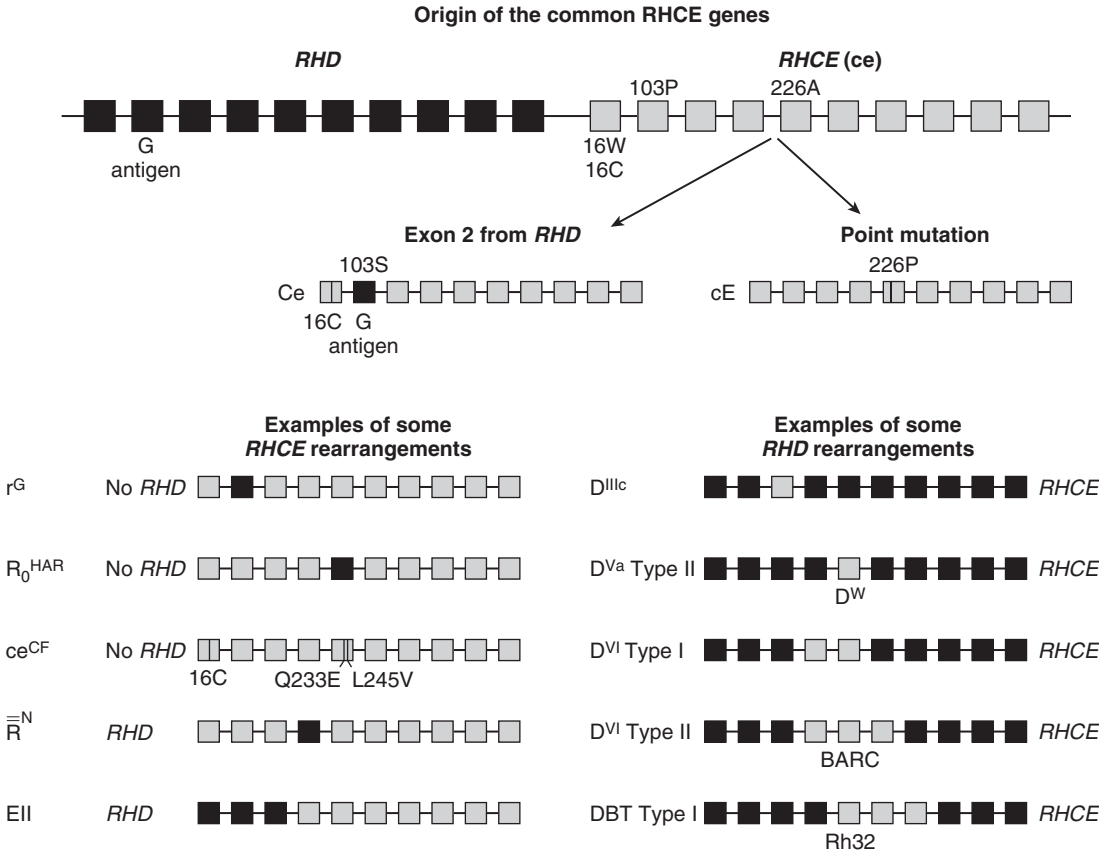

Figure 7–2 *Top panel,* Diagram of the *RHD* and *RHCE* genes, indicating the changes that resulted in the common RhCE polymorphisms. The shared exon 2 of *RHD* and *RHCE* (shown as a *black box*) explains the expression of G antigen on RhCe and RhD proteins. *Bottom panel,* Examples of some *RHCE* and *RHD* rearrangements.

Table 7–3 Molecular Basis of Some Rh Antigens, Partial D, and Unusual Phenotypes

Molecular Basis	Gene	Phenotype/Antigen/Genotype
Single point mutations	*RHD*	Partial D: DMH, D^{VII}, D+G–, DFW, DHR, D^{Va}, D^{HMi}, DNU, D^{II}, DNB, DHO Weak D (previously called D^{u})
	RHCE	C^{X}, C^{W}, Rh–26, E type I, IV, V+,VS+
Multiple mutations (gene conversions)	RHD RHCE	Partial D: D^{IIIa}, D^{IVa}, D^{Va}, DFR type I E type III, IV, V+VS+
Rearranged gene(s) *RHD*	RHD-CE-D	Partial D: D^{IIIb}, D^{IIIc}, D^{IVb}, D^{Va}, D^{VI}, DFR type II, DBT r″^{G}, (Ce)Ce, (C)ce^{s} VS+V–

Table 7–4 Composition (IgM and IgG Clones) and Reactivity of FDA-Licensed Anti-D Reagents with Some Rh Variant RBCs That Can Result in D Typing Discrepancies

Reagent	IgM Monoclonal	IgG	DVI	DBT	DHAR (Whites)	Crawford (Blacks)
Gammaclone	GAMA401	F8D8 monoclonal	Neg/Pos*	Pos	Pos	Pos
Immucor Series 4	MS201	MS26 monoclonal	Neg/Pos	Pos	Pos	Neg
Immucor Series 5	Th28	MS26 monoclonal	Neg/Pos	Pos	Vary/Pos	Neg
Ortho BioClone	MAD2	Polyclonal	Neg/Pos	Neg/Pos	Neg/Neg	Neg
Ortho Gel (ID-MTS)	MS201		Neg	Pos	Pos	Neg
Polyclonal			Neg/Pos	Neg/Pos	Neg/Neg	Neg/Neg

* Result following slash denotes anti-D test result by the IAT, as permitted by the manufacturer.

Lastly, an Rhce protein with an R154T mutation, designated ceRT, demonstrates weak reactivity with some anti-D monoclonal reagents, and the reactivity is enhanced at lower temperatures. Interestingly, this variant does not carry any D-specific amino acid but mimics a D-epitope (epD6) structure.[47]

C/c and E/e Antigens

There are four major allelic forms of *RHCE*: ce, Ce, cE, and CE.[14] C and c differ by four amino acids: Cys16Trp (cysteine at residue 16 replaced by tryptophan) encoded by exon 1, and Ile60Leu, Ser68Asn, and Ser103Pro encoded by exon 2. Only residue 103 is predicted to be extracellular; it is located on the second loop of RhCE (see Fig. 7–1). The amino acids encoded by exon 2 of *RHC* are identical to those encoded by exon 2 of *RHD*. At the genomic level, *RHCe* appears to have arisen from transfer of exon 2 from *RHD* into *RHce* (see Fig. 7–2). The shared exon 2 explains the expression of the G antigen on both RhD and RhC proteins.

E and e differ by one amino acid, Pro226Ala. This polymorphism, predicted to reside on the fourth extracellular loop of the protein (see Fig. 7–1), is encoded by exon 5. A single point mutation in *RHce* resulted in *RHcE* (see Fig. 7–2).[14,48]

C^W and C^X antigens result from single amino acid changes, encoded by exon 1, which are predicted to be located on the first extracellular loop of the RhCE protein.[49]

The antigens V and VS are expressed on RBCs of more than 30% of black persons. They are the result of a Leu245Val substitution located in the predicted eighth transmembrane segment of Rhce.[50] The close location of the e antigen, Ala226 on the fourth extracellular loop, suggests that Leu245Val causes a local conformation change responsible for the weakened expression of e antigen in many black persons who are V and VS positive. The V−VS+ phenotype results from a Gly336Cys change on the 245Val background,[51] and these alleles are referred to as ce^S (Fig. 7–3). Loss of VS expression (the V+VS− phenotype) is associated with additional amino acid changes and is characteristic of the ceAR haplotype (see Fig. 7–3).

Other modifications of *RHCE*, which are uncommon, are the hybrids r^G, R^N, and several E/e variants (see Fig. 7–2). R^N RBCs are found in people of African origin and type as e-weak (or negative) with polyclonal reagents, but are indistinguishable from "normal" e-positive RBCs with some monoclonal anti-e. The E variants—EI, EII, and EIII—result either from a point mutation (EI) or from gene conversion events that lead to replacement of several extracellular RhcE amino acids with RhD residues (EII and EIII) and loss of some E epitope expression.[52] Category EIV RBCs, which have an amino acid substitution in an intracellular domain, do not lack E epitopes but have reduced E expression.[53] The very rare RH:-26 results from a Gly96Ser transmembrane amino acid change that abolishes Rh26 and weakens c expression.[54]

VARIATION IN e EXPRESSION AND SICKLE CELL PATIENTS

Variation in expression of the e antigen is not uncommon and can result from several different mutations. Deletion of the codon for Arg229, which is close to the Ala226 residue found in normal e expression,[55] and substitution of a Cys residue for Trp at position 16 in the Rhce protein[56] weaken expression of the antigen. Individuals of African ancestry often have *RHce* genes that encode variant e antigens. The RBCs type as e positive, but they often make alloantibodies with e-like specificities. The antibodies, designated anti-hr^S, -hr^B, -RH18, and -RH34, are difficult to identify serologically, are clinically significant, and have caused transfusion fatalities.[57] The prevalence of e variants in this population, together with the incidence of sickle cell disease requiring transfusion support often provided by white donors with conventional *RHce*, make the occurrence of alloanti-e in these patients not uncommon. Some of the *RH* genetic backgrounds have now been defined[58] and include the *RHCE* haplotypes shown in Figure 7–3. All encode the Trp16Cys difference in exon 1, and have additional changes, primarily localized to exon 5. The ce^S allele is associated with RBCs that are hr^B–, whereas individuals homozygous for ceAR, ceMO, ceEK, and ceBI alleles lack

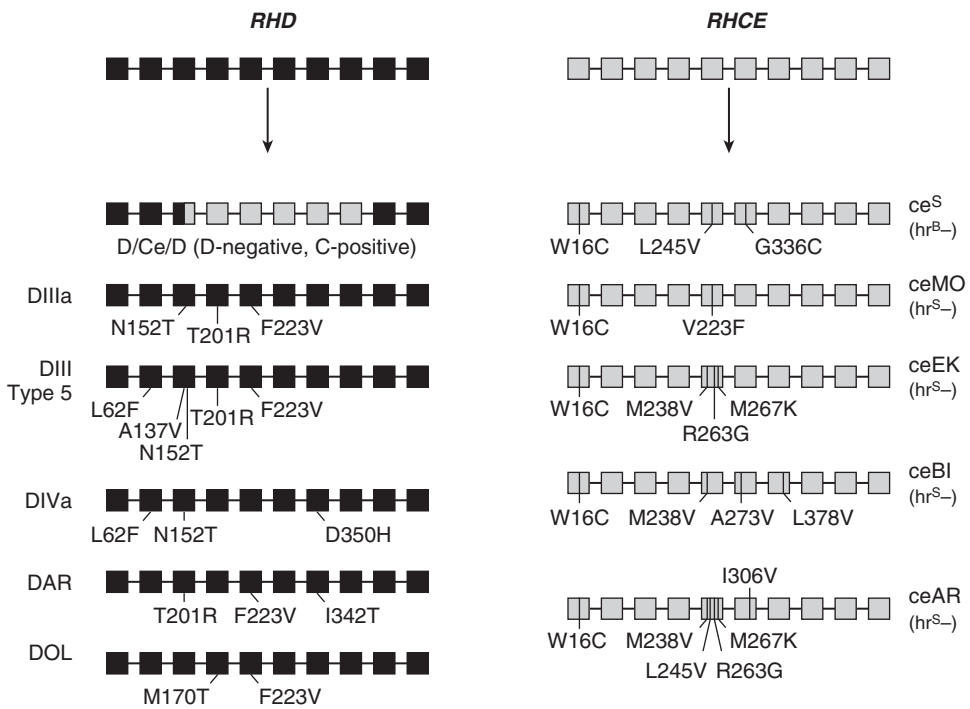

Figure 7–3 Diagram of the *RHD* and *RHCE* genes indicating changes often found in African backgrounds that complicate transfusion in sickle cell patients.

the high-incidence hr^S antigen (see Fig. 7–3). Importantly, because of the multiple molecular backgrounds responsible for the hr^B– and hr^S– phenotypes, some of which are not yet elucidated, the antibodies produced are not all serologically compatible. This explains why it is difficult to find compatible blood for patients with these antibodies, and often only rare deleted D– – RBCs appear compatible. As an additional complication, these variant *RHce* can often be inherited with an altered *RHD* (e.g., DAR, DAU, or DIIIA), so they can also make anti-D (see Fig. 7–3).

Rh Genotyping

RH genotyping is a useful means to determine the Rh phenotype of patients who have been recently transfused or whose RBCs are coated with IgG. RH genotyping in the prenatal setting can be used to determine paternal *RHD* zygosity and to predict fetal D status to prevent invasive and expensive monitoring for the possibility of HDN. The ethnic background of the parents is important to the design of the assay, because the different molecular events responsible for D-negative phenotypes must be considered. Testing of samples from the parents limits the possibility of misinterpretation.

RH genotyping can aid resolution of D typing discrepancies. These often are the result of differences in manufacturers' reagents, but in the donor setting they can be FDA reportable. Genotyping can determine a specific weak D type, partial D category, or the presence of D_{el}.

Genotyping to detect the inheritance of altered or variant e alleles, which are often linked to variant *RHD,* aids resolution of antibody specificities and is helpful to determine alloantibody versus autoantibody specificity. This can be of significance, especially in sensitized sickle cell patients. Molecular genotyping can aid in the selection of compatible blood for transfusion and ultimately improve long-term transfusion support. Currently, these investigations can sometimes be cumbersome, often requiring complete gene sequencing. The development of automated, high-throughput platforms that sample many regions of both *RHD* and *RHCE,* along with detailed algorithms for accurate interpretation, are needed.

Antibodies

Most Rh antibodies are IgG, subclasses IgG1 and IgG3 (IgG2 and IgG4 have also been detected), and some sera have an IgM component.[59] Rh antibodies do not activate complement, although two rare exceptions have been reported. The lack of complement activation by Rh antibodies is thought to be due to the distance between antigens, but is probably due to a lack of mobility.[6] Reactivity of Rh antibodies is enhanced by enzyme treatment of the test RBCs, and most react optimally at 37°C.

Anti-D can cause severe transfusion reactions and severe HDN. Approximately 80% to 85% of D-negative persons make anti-D after exposure to D-positive RBCs. The lack of response in 15% may be due to antigen dose, recipient HLA-DR alleles, and other as yet unknown genetic factors. Anti-D was the most common Rh antibody, but its incidence has greatly diminished with the prophylactic use of Rh immune globulin for prevention of HDN. ABO incompatibility between the mother and the fetus has a partial protective effect against immunization to D; this finding suggested the rationale for development of Rh immune globulin.[59]

Anti-c, clinically the most important Rh antibody after anti-D, may cause severe HDN. Anti-C, anti-E, and anti-e do not often cause HDN, and when they do, it is usually mild.[6,59]

Autoantibodies to high-incidence Rh antigens often occur in the sera of patients with warm autoimmune hemolytic anemia and in some cases of drug-induced autoimmune hemolytic anemia. These autoantibodies are nonreactive with Rh-null cells.[60]

Anti-D reagents

A large number of IgM, direct-agglutinating, anti-D monoclonals have been generated by immortalizing human B lymphocytes in vitro with Epstein-Barr virus. D-typing reagents licensed for use in the United States are a blend of monoclonal IgM reactive at room temperature along with monoclonal or polyclonal IgG reactive by the IAT for the determination of weak D. Four different FDA-licensed reagents are available for tube testing and one for gel (see Table 7–4). All but two contain different IgM clones. The reactivity of each with variant D antigens may result in D typing discrepancies. Importantly, the *IgM* anti-D component of these reagents has been selected to not react with D^{VI} RBCs (see Table 7–4). D^{VI} is the most common partial D found in white populations, and these individuals often make anti-D when exposed to conventional D. Most agree that they should be classified as Rh-negative for transfusion or Rh immune globulin. The *IgG* component in these reagents reacts with D^{VI} RBCs in the IAT phase (see Table 7–4). D^{VI} RBCs can stimulate production of anti-D in an Rh-negative recipient and must be typed as Rh-positive as donors. The composition of current FDA-licensed reagents has prompted the movement away from weak D testing in the hospital and prenatal setting to classify individuals with D^{VI} RBCs, or some of the other partial D phenotypes (see Table 7–4), as Rh negative.

Monoclonal anti-D has not yet been tested clinically for its ability to prevent immunization after pregnancy but has been shown to suppress D immunization in D-negative male volunteers.[61]

Expression

Northern blot analysis indicated that Rh and RhAG messenger RNA (mRNA) are restricted to cells of erythroid and myeloid lineage, but reverse transcriptase-PCR (RT-PCR) found Rh mRNA splicing isoforms in B and T lymphocytes and monocytes.[62] The significance of this observation is not yet known. During erythropoiesis, RhAG appears early (on $CD34^+$ progenitors), but the Rh proteins appear later—RhCE first, followed by RhD.[63]

Evolution

The *RHD* and *RHCE* genes arose from an early duplication of the erythrocyte *RHAG* gene. *RH* and *RHAG* have been investigated in nonhuman primates[64,65] and rodents,[66–68] and most, with the exception of gorillas and chimpanzees, have a *RHAG* and only one *RH* gene. The *RH* gene duplicated in some common ancestor of gorillas, chimpanzees, and humans, leading to *RHCE* and *RHD*. Chimpanzees and some gorillas have three *RH* genes, indicating that a third duplication has taken place in these species.

Function

The predicted membrane structures of Rh and RhAG suggest that they are transport proteins, and the analysis of their

amino acid sequence reveals distant similarity to ammonium transporters in bacteria, fungi, and plants.[69] Evidence for ammonia transport by RhAG comes from yeast complementation experiments,[70,71] expression studies in *Xenopus* oocytes,[72] and direct evidence in RBCs.[73] Rh and RhAG homologues have been found in many organisms, including the sponge *(Geodia)*, the slime mold *(Dictyostelium*), the fruit fly *(Drosophila)*, and the frog *(Xenopus)*,[74] indicating that they are conserved throughout evolution.

Nonerythroid homologues, designated RhCG and RhBG, are found in the kidney,[75] liver,[76,77] testis, brain, gastrointestinal tract,[78] and skin[79,80] and are localized to regions where ammonium production and elimination are critical in mammalian tissues, strongly suggesting a role for these proteins in ammonia/ammonium homeostasis. When expressed in *Xenopus* oocytes, RhBG and RhCG also mediate transport of ammonia.[81] In the kidney ammonium ions act as expendable cations that facilitate excretion of acids, and renal ammonium metabolism and transport are critical for acid-base balance. In the collecting segment and collecting duct, where large amounts of ammonia are excreted, RhBG and RhCG are found on the basolateral and apical membranes, respectively, of the intercalated cells.[76] These localization studies suggest that RhBG and RhCG are ideally situated to mediate transepithelial movement of ammonium from the interstitium to the lumen of the collecting duct. In support, mouse collecting duct (mIMCD-3) cells, which show polarized expression of these proteins, demonstrate transporter-mediated movement of ammonia.[82]

The function of RhCE and RhD has not been determined. Co-expression of RhCE/RhAG did not influence the rate or total substrate accumulated in oocytes compared to that seen with expression of RhAG alone.[83] Although further studies are necessary to determine if RhCE/D are involved in membrane transport, RhCE/D may have lost transport function and may have a structural role in the RBC membrane.

Summary

The molecular basis of many of the Rh antigens has now been elucidated. The revelation that RhD and RhCE proteins differ by 35 amino acids explains why D antigen is so immunogenic. In addition, exchanges between *RHD* and *RHCE*, mainly by gene conversion, have generated many Rh polymorphisms. The proximity of the two genes on the same chromosome probably affords greater opportunity for exchange. This finding finally explains the myriad of antigens observed in the Rh blood group system and gives interesting insight into the evolutionary history of duplicated genes and the interactions that can take place between them. The complexity hampers molecular genotyping, and additional Rh variants are still being discovered. The challenge is to develop automated platforms that sample several regions of the genes for unequivocal interpretation.

The discovery that members of the Rh family of proteins, RhAG, RhBG, and RhCG, are involved in ammonia/ammonium transport and are ideally positioned in key tissues essential for ammonium elimination is a significant finding because it was long assumed that the high membrane permeability of ammonia would obviate the need for specific transport pathways in mammalian cells.

RBC membrane protein–cytoskeleton and protein–protein interactions are an active area of investigation. Although the major attachment sites between the erythrocyte cytoskeleton and the lipid bilayer are understood to be through glycophorin C and band 3, an additional attachment site mediated by the Rh complex explains the Rh-null defect. Additional studies are needed to determine the protein–protein associations and the dynamics of the assembly of the Rh-membrane complex.

THE KELL AND Kx SYSTEM

History

The Kell blood group system was discovered in 1946, just a few weeks after the introduction of the antiglobulin test. The RBCs from a newborn baby who was thought to be suffering from HDN gave a positive reaction in the direct antiglobulin test.[84] The serum of the mother reacted with RBCs from her husband, her older child, and 9% of random donors. The system was named from Kelleher, the mother's surname, and the antigen is referred to as K (synonyms: Kell, K1). Three years later, the more common antigen, k (synonyms: Cellano, K2), which has a high incidence in all populations, was identified through the typing of large numbers of RBC samples with an antibody that had also caused a mild case of HDN.[85] The Kell system remained a simple two-antigen system until 1957, when the antithetical Kp^a and Kp^b antigens were reported, as was the K_0 (Kell-null) phenotype.[6] Subsequently, the number of Kell antigens has grown to 25, making Kell one of the most polymorphic blood group systems known.

Proteins

The Kell protein is a type II glycoprotein with an approximate M_r of 93,000. It has a 665-amino acid carboxyl terminal extracellular domain, a single 20-amino acid transmembrane domain, and a 47-amino acid N-terminal cytoplasmic domain.[86] The protein has five N-glycosylation sites and 15 extracellular cysteine residues that cause folding through the formation of multiple intrachain disulfide bonds (Fig. 7–4). This explains why Kell blood group antigens are inactivated when RBCs are treated with reducing agents, such as dithiothreitol and aminoethylisothiouronium bromide, which disrupt disulfide bonds.[87] All Kell system antigens are carried on this glycoprotein, which is present at 3500 to 17,000 copies per RBC.[88,89] All but two (Js^a and Js^b) of the Kell antigens are localized in the N-terminal half of the protein before residue 550, strongly suggesting that the C-terminal domain does not tolerate change and is functionally important. Indeed, the Kell glycoprotein is a zinc endopeptidase, and the C terminus contains a zinc-binding domain that is the catalytic site.[90,91]

Kx is a 444-amino acid, 37-kD protein that is linked by a disulfide bond to the Kell protein.[17] Kx is predicted to span the membrane 10 times (see Fig. 7–4), is not glycosylated, and may be a membrane transport protein. RBCs lacking Kx have the McLeod phenotype, which is characterized by a marked reduction of Kell antigens, acanthocytosis, and reduced in vivo RBC survival.

Genes

The *KEL* gene has been localized on chromosome 7q33. It consists of 19 exons spanning approximately 21.5 kb.[92,93] The Kell antigens result from nucleotide mutations that cause

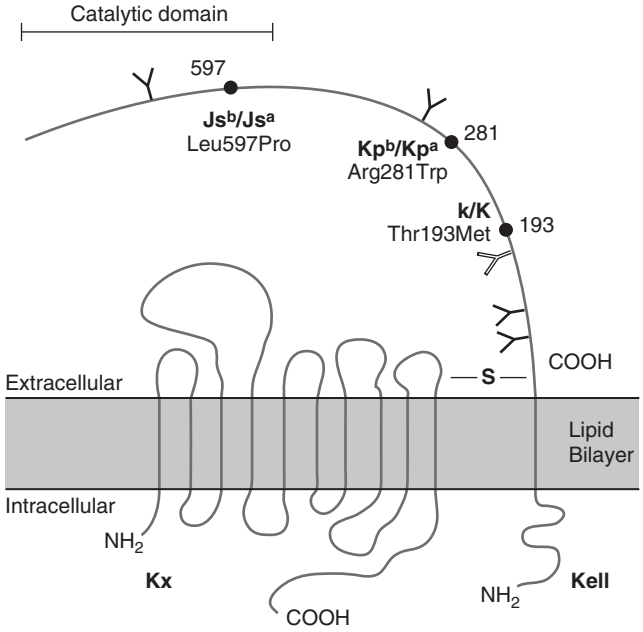

Figure 7–4 Kell and Kx proteins. Kell is a single-pass protein, but Kx is predicted to span the red blood cell membrane 10 times. Kell and Kx are linked by a disulfide bond, shown as -S—. The amino acids that are responsible for the more common Kell antigens are shown. The N-glycosylation sites are shown as *Y*. The *hollow Y* represents the N-glycosylation site that is not present on the K (K1) protein.

single amino acid substitutions in the protein (Table 7–5). The lack of Kell antigens, K_0, is caused by several different molecular defects, including nucleotide deletion, defective splicing, premature stop codons, and amino acid substitutions.[91,94,95]

The *XK* gene is on the short arm of the X chromosome at Xp21.[96] *XK* has three exons, and mutations cause the McLeod syndrome, which, because the gene is X linked, affects males. Carrier females, because of X-chromosome inactivation, have two populations of RBCs (one of the McLeod phenotype and one normal), and the proportion varies from 5% McLeod:95% normal to 85% McLeod:15% normal.[97,98]

McLeod Syndrome

When testing medical students in 1961, Allen and coworkers[99] found that one of the students, Mr. McLeod, had RBCs with very weak expression of Kell antigens. It is now evident that he lacked Kx, which is important for expression of Kell, and that lack of Kx is the basis for the McLeod syndrome. Males with the McLeod syndrome have muscular and neurologic defects, including skeletal muscle wasting, elevated serum creatine phosphokinase, psychopathology, seizures with basal ganglia degeneration, and cardiomyopathy.[90,100] Most symptoms develop after the fourth decade of life. The syndrome is very rare. Approximately 60 males have been identified, and all but 2 have been white; however, because of the plethora of symptoms, the syndrome is probably underdiagnosed.

Fifteen different mutations in the *XK* gene were found in a study of 17 families; these mutations involve major and minor deletions, point mutations, and splice site or frameshift mutations that result in the absence or truncation of Kx protein.[17,100] At one time, chronic granulomatous disease (CGD) was thought to be related to the McLeod syndrome, but the gene controlling CGD is near the *XK* gene on the X chromosome, and the small minority of patients with CGD who have the McLeod phenotype have X-chromosome deletions encompassing both genes.[6,101]

Table 7–5 **Molecular Basis of Antigens in the Kell Blood Group System**

Antigen	Amino Acid	Position
k(K2)	Threonine	193
K(K1)	Methionine	
Kp^a(K3)	Tryptophan	281
Kp^b(K4)	Arginine	
Kp^c(K21)	Glutamine	
Js^a(K6)	Proline	597
Js^b(K7)	Leucine	
K11	Valine	302
K17	Alanine	
K14	Arginine	180
K24	Proline	
Ul^a	Glutamic acid→Valine	494

Antigens

The Kell system consists of five sets of high-incidence and low-incidence antigens, as follows (the names of the high-incidence antigens appear in **boldface**):

- K and **k**
- Kp^a, **Kp^b**, and Kp^c
- Js^a and **Js^b**
- **K11** and K17
- **K14** and K24

In addition, 14 independently expressed antigens, 3 low-incidence (Ul^a, K23, VLAN), and 11 high-incidence (Ku, Km, K12, K13, K16, K18, K19, K22, Tou, KALT, KTIM), have been identified. The null phenotype, K_0, lacks Kell antigens, and Kell-mod phenotypes have a weak expression of Kell antigens.

Kell antigens show population variations (Table 7–6). K has an incidence of 9% in white persons but is much less common in people of other ethnic backgrounds.[1,58] Kp^a and K17 are also mainly found in white persons. Js^a is almost exclusively found in African Americans, with an incidence of 20%. Ul^a is found in Finnish and Japanese persons.[1,58]

The molecular basis of most of the Kell antigens has been determined (see Table 7–5).[91,102] The K methionine substitution disrupts a glycosylation consensus sequence so that K has one less N-glycan than k.[103] Js^a and Js^b are located within a cluster of cysteine residues,[104] a finding that explains why they are more susceptible than other Kell antigens to treatment with reducing agents.[105] No Kell haplotype has been found to express more than one low-incidence Kell antigen, not because of structural constraints, but because multiple expression would require more than one mutation encoding a recognized Kell system antigen to occur in the same gene.[106]

Weaker expression of Kell antigens is found when RBCs carry Kp^a in *cis*.[107–109] Weak expression of Kell antigens can be inherited or can be acquired and transient. Inherited weak expression occurs when the Kell-associated Kx protein is absent (McLeod phenotype), when glycophorins C and D are absent (Leach phenotype), or when a portion of the extracellular domain of glycophorin C and D, specifically exon 3, is

Table 7–6 **Kell Phenotypes and Prevalence**

Phenotype	Prevalence (%) White	Prevalence (%) African American
K–k+	91	98
K+k+	8.8	2
K+k–	0.2	Rare
Kp(a+b–)	Rare	0
Kp(a–b+)	97.7	100
Kp(a+b+)	2.3	Rare
Kp(a–b–c+)	0.32 Japanese	0
Js(a+b–)	0	1
Js(a–b+)	100	80
Js(a+b+)	Rare	19
K11	High incidence	
K17	Low incidence	
K14	High incidence	
K24	Low incidence	
Ul[a]	Low incidence (2.6% in Finns, 0.46% in Japanese)	

deleted (some Gerbich-negative phenotypes).[109,110] Transient depression of Kell system antigens has been associated with the presence of autoantibodies mimicking alloantibodies in autoimmune hemolytic anemia and with microbial infections. Kell expression was reduced in two cases of idiopathic thrombocytopenic purpura but returned to normal after remission.[6]

Antibodies

Kell antigens are highly immunogenic, and anti K is common. However, because more than 90% of donors are K negative, it is not difficult to find compatible blood for patients with anti-K. The other Kell system antibodies are less common but are also usually IgG, and they have caused transfusion reactions and HDN or neonatal anemia. In HDN due to Kell antibodies, neither maternal antibody titers nor amniotic bilirubin levels are good predictors of the severity of the disease. Reports demonstrate that Kell antigens are expressed very early during erythropoiesis[63] and that Kell antibodies can cause suppression of erythropoiesis in vitro.[111] This finding suggests that the low level of bilirubin observed, in the presence of neonatal anemia, is due to Kell antibodies that bind to erythroid progenitors and exert effects before hemoglobinization.

Anti-Ku is the antibody made by immunized K_0 individuals, and Ku represents the high-incidence or "total-Kell" antigen. McLeod males with CGD make anti-Kx+Km; this antibody reacts strongly with K_0 cells, weaker with RBCs of common Kell phenotype, and not at all with McLeod phenotype RBCs. Anti-Km, made by McLeod persons who do not have CGD, reacts with RBCs of common Kell phenotypes but not with K_0 or McLeod RBCs, suggesting that it detects one or more epitopes requiring both the Kell and Kx proteins. One case has been reported of a McLeod male without CGD who made an apparent anti-Kx without the presence of anti-Km.[101]

Expression

Kell system antigens appear to be erythroid specific and are expressed very early during erythropoiesis.[63] Kx mRNA is found in muscle, heart, brain, and hematopoietic tissue.[17]

Evolution

Primate RBCs express the k antigen but not the K antigen, indicating that the K mutation appeared in human lineage. Chimpanzees are Js(a+b–),[112] and Js^a is also present on RBCs from Old World monkeys,[113] suggesting that Js^b also arose after human speciation. Kell protein is not found on immunoblots of RBCs from sheep, goat, cattle, rabbit, horse, mouse, donkey, cat, dog, or rat.[114]

Function

The Kell glycoprotein is a member of the M13 or neprilysin family of zinc endopeptidases that cleave a variety of physiologically active peptides. One member of this family, endothelin converting enzyme 1 (ECE-1), is a membrane-bound metalloprotease that catalyzes the proteolytic activation of big endothelin-1 (big ET-1).[115] Like ECE-1, Kell protein can proteolytically cleave endothelins, specifically big ET-3 to generate ET-3, which is a potent vasoconstrictor.[116] ET-3 is also involved in the development of the enteric nervous system and in migration of neural crest-derived cells. The biologic role of the endothelins is not yet completely elucidated, but they act on two G protein–coupled receptors, ET_A and ET_B, which are found on many cells. Kell-null individuals, who lack Kell protein, do not have any obvious defect, so they do not immediately give insight into the biologic function of the Kell protein. This lack of defect in Kell-null people may be because other enzymes probably also cleave ET-3,[116] and determining whether Kell-null individuals have abnormal levels of plasma endothelins is an active area of investigation.

DUFFY (Fy) BLOOD GROUP SYSTEM

History

The Duffy (Fy^a) blood group antigen was first reported in 1950 by Cutbush and associates,[117] who described the reactivity of an antibody found in a hemophiliac male who had received multiple transfusions. This blood group system bears the patient's surname, Duffy, the last two letters of which provide the abbreviated nomenclature (Fy). Fy^b was found 1 year later.[118] In 1975, Fy was identified as the receptor for the malarial parasite *Plasmodium vivax*.[119] This discovery explained the predominance of the Fy(a–b–) (Fy-null) phenotype, which confers resistance to malarial invasion, in persons originating from West Africa.

Proteins

The Fy protein is a transmembrane glycoprotein of 35 to 43 kD consisting of a glycosylated amino terminal region, which protrudes from the membrane and has seven transmembrane-spanning domains (Fig. 7–5).[120,121] In 1993, it was realized that Fy was the erythrocyte chemokine receptor that could bind interleukin-8 and monocyte chemotactic peptide-1 (MCP-1).[122] The cloning of the *FY* gene[123] confirmed that it belongs to the conserved family of chemokine receptors.

Gene

The *FY* gene is located on the long arm of chromosome 1q22–q23[124] and spans 1.5 kb. The gene, which has only two

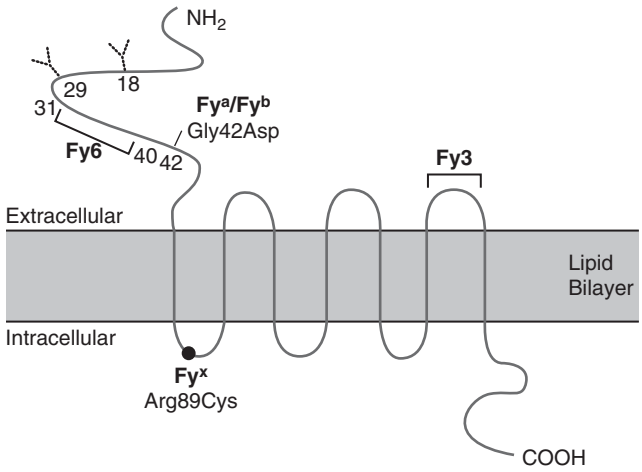

Figure 7–5 The predicted seven-transmembrane domain structure of the Duffy protein. The amino acid change responsible for the Fy^a/Fy^b polymorphism, the mutation responsible for Fy^x glycosylation sites, and the regions where Fy3 and Fy6 map are indicated.

exons, contains two ATG codons. The upstream exon contains the major start site.[125,126] The same two-exon organization is also found in genes for other chemokine receptors.[127]

Antigens

The Fy^a and Fy^b antigens are encoded by two allelic forms of the gene, designated *FYA* and *FYB*, and are responsible for the Fy(a+b−), Fy(a−b+), and Fy(a+b+) phenotypes.[126] They differ by a single amino acid located on the extracellular domain (see Fig. 7–5).

Fy^x, which is a weak expression of Fy^b, is found in white persons and is due to a single mutation in the *FYB* gene.[128,129] The amino acid change, which is located in the first intracellular cytoplasmic loop, is associated with a decrease in the amount of protein in the membrane and results in diminished expression of Fy^b, Fy3, and Fy6 antigens as well as reduced binding of chemokine.[127,130,131]

Fy3, as determined with one monoclonal anti-Fy3, is located on the third extracellular loop,[132] whereas Fy6 maps to the amino terminal loop of the protein. The aspartic acid at amino acid 25 and glutamic acid at 26 are critical for anti-Fy6 binding.[133]

The Fy(a−b−) phenotype found in African Americans is caused by a mutation in the promoter region of *FYB* (T>C at position −46), which disrupts a binding site for the erythroid transcription factor GATA-1 and results in the loss of Fy expression on RBCs.[134,135] The Fy protein has also been found on endothelial cells. Because the erythroid promoter controls expression only in erythroid cells, expression of Fy proteins on endothelium is normal in these Fy(a−b−). All African persons with a mutated GATA sequence to date have been shown to carry *FYB;* therefore, Fy^b is expressed on their nonerythroid tissues. This finding explains why Fy(a−b−) individuals make anti-Fy^a but not anti-Fy^b.[136] It also is relevant in the selection of antigen-matched units for Fy(a−b−) patients with sickle cell disease, because they would not be expected to make anti-Fy^b. Rare Fy(a−b−) who do make anti-Fy^b should be investigated at the genetic level, because the molecular basis for this observation has not yet been explained. Lastly, a *FYA* allele with a mutated GATA sequence has been found in Papua New Guinea.[137]

Table 7–7 Duffy Phenotypes and Prevalence

	Prevalence (%)				
Phenotype	**Caucasians**	**Blacks**	**Chinese**	**Japanese**	**Thai**
Fy(a+b−)	17	9	90.8	81.5	69
Fy(a−b+)	34	22	0.3	0.9	3
Fy(a+b+)	49	1	8.9	17.6	28
Fy(a−b−)*	Rare	68	0	0	0
Fy^X	1.4	0	0	0	0

*Fy(a−b−), incidence in Israeli Arabs 25%; Israeli Jews, 4%

The Fy(a−b−) phenotype in white persons is very rare (Table 7–7).[1] One propositus, an Australian (AZ) woman, appears to be homozygous for a 14-bp deletion in *FYA*, which introduces a stop codon in the protein[138]; a Cree Indian female (Ye), a white female (NE), and a Lebanese Jewish male (AA) carry different Trp to stop codon mutations.[139] Because these mutations would result in a truncated protein, these people would not be expected to express endothelial or erythroid Fy protein. All four people made anti-Fy3.

There are 13,000 to 14,000 Fy antigen sites per RBC,[140] and Fy^a, Fy^b, and Fy6 antigens are sensitive to proteolytic enzyme treatment of antigen-positive RBCs, although Fy3 is resistant.

Antibodies

Fy antigens are estimated to be 40 times less immunogenic than K antigens, and most Fy antibodies arise from stimulation by blood transfusion. They are mostly IgG, subclass IgG1, and only rarely are IgM. Anti-Fy^b is less common than anti-Fy^a, and Fy antibodies are often found in sera with other antibodies. Anti-Fy3 is made by rare white Fy(a−b−) individuals.[6] Anti-Fy6 is a mouse monoclonal antibody.[127]

Expression

Duffy mRNA is present in kidney, spleen, heart, lung, muscle, duodenum, pancreas, placenta, and brain.[123,127] Cells responsible for Fy expression in these tissues are the endothelial cells lining postcapillary venules,[141–143] except in the brain, where expression is localized to the Purkinje cell neurons.[144,145] The same polypeptide is expressed in endothelial cells and RBCs, but in brain, a larger, 8.5-kb mRNA is present. The function of Fy on neurons is an area of active investigation.

In the fetus, Fy antigens can be detected at 6 to 7 weeks' gestation and are well developed at birth.[1] The expression of these antigens was found to occur late during erythropoiesis and RBC maturation.[63]

Evolution

RBCs of monkeys and apes react with anti-Fy^b, and the conserved GT repeat sequences in the 3 flanking region of the gene both suggest that *FYB* was the ancestral gene.[146,147] The first human divergence occurred when a mutation in the erythroid promoter region of *FYB* resulted in the loss of Fy^b expression on RBCs. This mutation conferred resistance to malaria infection in regions where *P. vivax* was endemic and selected for the high proportion of Fy(a−b−) in populations of African ancestry. Later, a single nucleotide change

in the *FYB* gene caused the *FYA* polymorphism in people of European and Asian ancestry. Fy has been cloned from several nonhuman primates, including chimpanzees, squirrel monkeys, and rhesus monkeys, and from cows, pigs, rabbits, and mice.[127]

Function

The importance of Fy as a receptor for the malarial parasite *P. vivax* is well established, but its biologic role as a chemokine receptor on RBCs, endothelial cells, and brain is not yet clear. The chemokine receptors are a family of proteins that are receptors on target cells for the binding of chemokines. Chemokines are so named because they are *cytokines* that are *chemotactic* (cause cell migration), and their receptors are an active area of investigation.[148] Chemokine receptors have been found principally on lymphocytes, where they are coupled to G proteins and activate intracellular signaling pathways that regulate cell migration into tissues. Unlike other chemokine receptors, Fy does not have a conserved amino acid DRY-motif in the second extracellular loop, and cells transfected with Fy and stimulation with chemokines do not mobilize free calcium.[120] Also, Fy can bind chemokines from both the CXC (IL-8, MGSA) and the CC (RANTES, MCP-1, MIP-1) classes of chemokines.[127] These features have led investigators to hypothesize that it may act as a scavenger or sink for excess chemokine release into the circulation.[149,150] If the function of Fy on RBCs is to scavenge excess chemokine, it may be that Fy(a−b−) individuals would be more susceptible to septic shock[143] or to cardiac damage after infarction. Renal allografts have been reported to have shorter survival in African American Fy(a−b−) recipients,[151] and Fy has been shown to be upregulated in the kidney during renal injury.[152]

Abundant expression of Fy on high endothelial venules and sinusoids in the spleen,[143] which is a site central to chemokine-induced leukocyte trafficking, suggests a role in leukocyte migration into the tissues. Fy is also similar to the receptor for endothelins (ET_B), vasoactive proteins that strongly influence vascular biology and that may also be mitogenic.[127]

THE KIDD BLOOD GROUP SYSTEM

History

The Kidd blood group system was discovered in 1951, when a "new" antibody in the serum of Mrs. Kidd (who also had anti-K) caused HDN in her sixth child. Jk came from the initials of the baby (John Kidd), because K had been used previously for Kell.[153] Anti-Jk^b was found 2 years later in the serum of a woman who had a transfusion reaction (she also had anti-Fy^a).[154] Kidd system antibodies are characteristically found in sera with other blood group antibodies, suggesting that Kidd antigens are not particularly immunogenic. However, Kidd antibodies induce a rapid and robust anamnestic response that is responsible for their reputation for causing severe delayed hemolytic transfusion reactions.

Proteins

The Kidd glycoprotein has an approximate M_r of 46,000 to 60,000 and is predicted to span the membrane 10 times. The third extracellular loop is large and carries an N-glycan at Asn211 (Fig. 7–6). The protein has 10 cysteine residues, but only 1 is predicted to be extracellular, a fact that explains why the antigens are not sensitive to disulfide reagents. There is internal homology between the N-terminal and C-terminal halves of the protein, with each containing an LP box (LPXXTXPF) characteristic of urea transporters.[155] Isolation of the Kidd protein from RBCs was elusive, and cloning of the Kidd gene was accomplished with primers complementary to the rabbit kidney urea transporter. A clone isolated from a human bone marrow library with the PCR product was confirmed by in vitro transcription–translation to encode a protein that carried Kidd blood group antigens.[156]

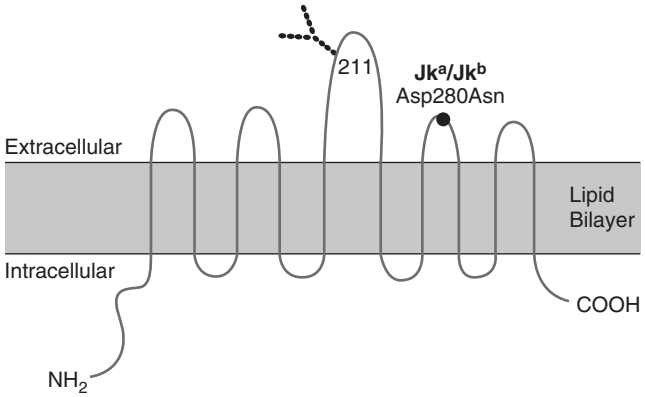

Figure 7–6 Predicted 10-transmembrane domain structure of the Kidd/urea transporter. The polymorphism responsible for the Kidd antigens and the site for the N-glycan are indicated.

Gene

The Kidd blood group gene (*HUT11* or *SLC14A1*) is located at chromosome 18q11–q12.[157,158] The *HUT11* gene has 11 exons and spans approximately 30 kb. Two alternative polyadenylation sites generate transcripts of 4.4 and 2.0 kb, which appear to be used equally. Exons 4 to 11 encode the mature protein.[17,159]

Antigens

Two antigens, Jk^a and Jk^b, are responsible for the three common phenotypes—Jk(a+b−), Jk(a−b+), and Jk(a+b+). The two antigens are found with similar frequency in white persons but show large differences in other ethnic groups (Table 7–8).[1] The Jk(a−b−) phenotype is rare but occurs with greater incidence in Asian and Polynesian people.

Table 7–8 Kidd Phenotypes and Prevalence

	Prevalence(%)		
Phenotype	**White**	**African**	**Asian**
Jk(a+b−)	26.3	51.5	23.2
Jk(a−b+)	23.4	8.1	26.8
Jk(a+b+)	50.3	40.8	49.1
Jk(a−b−)	Rare	Rare	0.9 (Polynesian)

The Jk^a and Jk^b polymorphism is located on the fourth extracellular loop and is caused by a single amino acid substitution (see Fig. 7–6).[160] The null phenotype has been reported to arise on the following two genetic backgrounds: homozygous inheritance of a silent allele and inheritance of a dominant inhibitor gene, *In(Jk)*, which is unlinked to *JK (HUT11)*.[1] The silent alleles were found to have acceptor or donor splice site mutations that cause skipping of exon 6 or exon 7.[159,161] In Finnish persons, a single point mutation (Ser291Pro) was the only change associated with silencing of the expression of Jk^b.[161] The unlinked dominant inhibitor gene has not yet been identified.

The Jk3 antigen ("total Jk") is found on RBCs that are positive for Jk^a, Jk^b, or both, but the specific amino acid residues responsible for Jk3 are unknown. There are approximately 14,000 Jk^a antigen sites on Jk(a+b−) RBCs.[140]

Antibodies

Neither anti-Jk^a nor anti-Jk^b is common, and anti-Jk^b is found less often than anti-Jk^a. Once a Kidd antibody is identified, compatible blood is not difficult to find, because 25% of donors are negative for each antigen. Unfortunately, Kidd antibodies are often found in sera that contain other alloantibodies, so the situation is often more complicated. In addition, the antibodies are known to cause delayed hemolytic transfusion reactions and are responsible for at least one third of all cases of delayed hemolytic transfusion reactions.[59] The antibodies often decrease in titer, react only with cells that are from persons homozygous for the antigen (the dosage phenomenon), or may escape detection altogether in the sensitized patient's serum before transfusion. If the patient is transfused with antigen-positive RBCs, an anamnestic response results, with an increase in the antibody titer and hemolysis of the transfused RBCs.[59]

Because Kidd antibodies are mainly IgG, it was assumed that they must activate complement to cause such prompt RBC destruction. Kidd antibodies can be partially IgM, however, and the minor IgM component may be responsible for the pattern of destruction of incompatible RBCs in delayed hemolytic transfusion reactions. This theory is based on evidence that serum fractions containing only IgG anti-Jk^a do not bind complement.[162] Kidd antibodies only rarely cause HDN; if they do, it is typically not severe. Anti-Jk^a has occasionally been found as an autoantibody, and the concurrent, temporary suppression of antigen expression has also been reported.[59] Anti-Jk3, sometimes referred to as anti-Jk^{ab}, is produced by Jk(a−b−) individuals and reacts with RBCs that are positive for Jk^a, Jk^b, or both.[163]

Expression

In the fetus, Kidd antigens can be detected at 11 weeks' gestation and are well developed at birth.[6] Immunohistochemical and in situ hybridization have shown that Kidd/HUT11 is also expressed on endothelial cells of vasa recta in the medulla of the human kidney.[17]

Evolution

Expression of RBC Kidd antigens has not been investigated in nonhuman primates, but the human RBC Kidd protein is clearly a member of a family of urea transporters, which have homologues in the human kidney and in nonhuman primates.

Function

A first clue to the function of Kidd came from the observation in 1982 that the RBCs of a male of Samoan descent were resistant to lysis in 2M urea, which was being used to lyse RBCs for platelet counting.[164] His RBCs were Jk(a−b−), and subsequent investigations revealed that movement of urea into Jk(a−b−) RBCs was equivalent to passive diffusion, in contrast to RBCs with normal Kidd antigens, with rapid urea influx. Fast urea transport in human RBCs is thought to be advantageous for RBC osmotic stability in the kidney, especially during transit through the vasa recta from the papilla to the isoosmotic renal cortex.[165] Urea transport in the kidney contributes to urine concentration and water preservation. Two types of urea transporters have now been characterized, vasopressin-sensitive transporters and constitutive transporters. The Kidd/HUT11 in RBCs and kidney medulla is a constitutive transporter. A vasopressin-sensitive transporter, HUT2, which is expressed in the collecting ducts of the kidney, has 62% sequence identity with Kidd/HUT11. *HUT2* is also located on chromosome 18q12, suggesting that both transporters evolved from an ancestral gene duplication.[166] Jk-null individuals do not suffer a clinical syndrome except for a reduced capacity to concentrate urine,[167] suggesting that other mechanisms or other gene family members, such as *HUT2*, can compensate for the missing Kidd/HUT11 protein.

Summary

The last decade has witnessed the rapid elucidation of the molecular basis for the various blood group antigens and phenotypes. In the next decade, research focus is turned to determination of the structure and function of the proteins carrying these blood group antigens. Null individuals *(natural knockouts),* persons who lack the antigens and the proteins that carry them, exist for all four of these blood group systems. Reminiscent of what is being found in many genetically engineered knockout mice, most of the individuals with null phenotypes do not have serious or any obvious defects. This observation is consistent with growing evidence that many genes have evolved as members of larger gene families, which appear to have overlapping abilities to substitute for the disrupted gene family member. Evidence is accumulating that genes encoding blood group proteins are also members of larger gene families. The mouse homologues of some of these blood group genes have been cloned, and knockout mice are being generated to study them. This process may aid in the further elucidation of the structure and function of the molecules carrying blood group antigens.

Chapter 8

Other Blood Group Antigens and Antibodies

Marion E. Reid • Connie M. Westhoff

This chapter provides information for the 16 blood group systems not covered in Chapters 6 and 7. The systems are discussed here in the order of their International Society of Blood Transfusion (ISBT) numbers (see Table 5–3). Antibodies to antigens in these systems are less common than those described in the preceding chapters, and information regarding their general clinical significance, when known, is summarized in Tables 5–5 and 5–6. The red blood cell (RBC) membrane components carrying the antigens of the systems described in this chapter are depicted in Figure 8–1. The antigens of the Chido-Rodgers system are adsorbed onto the RBC and are not integral membrane components; thus, they are not included in Figure 8–1.

THE MNS SYSTEM (ISBT SYSTEM 002)

History

The MNS system, discovered in 1927, was the second blood group system to be recognized. The first two antigens, M and N, were named from the second and fifth letters of the word *immune,* because the corresponding antibodies were produced through immunization of rabbits with human RBCs, and it was thought that the first letter, I, might be confused with the number 1.[1,2] The S antigen, the next to be identified, was named from the city (*S*ydney) where the first anti-S was discovered.[3] When the antithetical antigen was identified, the logical name s was used. The name for the high-incidence antigen U was derived from the "almost *universal* distribution of the new blood factor."[4] Many of the other antigens were named after the original family in which an antigen-positive neonate suffered from hemolytic disease of the newborn (HDN).

Gene, Protein, and Antigens

MNS antigens are carried on glycophorin A (GPA) and GPB, which are encoded by homologous genes (*GYPA* and *GYPB,* respectively) on chromosome 4q28–q31.[5] *GYPA* has seven exons, and *GYPB* has five exons and one pseudo-exon. A third homologous gene, *GYPE,* completes this glycophorin gene family, but it is not clear whether the product of *GYPE* is expressed on the RBC membrane. The glycophorin gene cluster encompasses approximately 330 kb in the following order: *GYPA*, *GYPB*, *GYPE.*[6]

Glycophorin A and GPB are single-pass membrane sialoglycoproteins oriented with their N termini to the exterior of the RBC. GPA has 15 potential sites for O-glycans, one N-glycan, and an approximate M_r of 43,000 on sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE); there are approximately 1million copies of GPA per RBC. GPB has 11 potential sites for O-glycans, no N-glycan, an approximate M_r of 25,000 on SDS-PAGE, and there are approximately 200,000 copies per RBC.[7,8]

M and N antigens are carried on alternative forms of GPA and are the result of amino acid substitutions at residues 1 and 5. The M antigen has Ser at position 1 and Gly at position 5, whereas the N antigen has Leu at position 1 and Glu at position 5. The first 26 amino acids of the N form of GPA are identical to those of GPB. Anti-N reagents prepared for use in the clinical setting are formulated to detect the N antigen on GPA but not the N on GPB (N).[9–13] Using these reagents, human RBCs type as M+N−, M−N+, or M+N+.

S and s antigens are carried on alternative forms of GPB. At amino acid residue 29, Met is critical for the S antigen and Thr for the s antigen. Both antigens also involve the amino acids at residues 25, 28, 34, and 35.[14] Persons who are S−s−, usually blacks, may be negative for the high-incidence antigen U owing to a deletion of or an altered form of *GYPB.*[15–17] Because M/N and S/s are on homologous proteins that are encoded by adjacent genes, they are inherited en bloc, accounting for linkage dysequilibrium between the antigens (Table 8–1).

The MNS blood group system is highly polymorphic, with 43 antigens.[7] Many of the antigens are uncommon, resulting from an amino acid substitution or multiple rearrangements between *GYPA* and *GYPB* (Table 8–2).[7,15] Low-incidence antigens in the MNS blood group system are as follows, in alphabetical order: Cl^a, DANE, Dantu, ERIK, Far, HAG, He, Hil, Hop, Hut, MARS, M^e, M^g, Mi^a, MINY, Mit, Mt^a, Mur, MUT, M^v, Nob, Ny^a, Or, Os^a, Ri^a, s^D, SAT, St^a, TSEN, Vr, Vw.[7] The rare null phenotypes of this system—En(a−), which lacks MN antigens; U−, which lacks S_s−antigens; and M^k M^k, which lacks both MN and Ss antigens—most often result from gene deletions.[7,18] Some antigens that are associated with the MNS system but are not numbered by the ISBT Working Party on Terminology for Red Cell Surface Antigens are a consequence of altered glycosylation at residues 2, 3, and 4 of GPA. They include Tm, Sj, M_1, Can, Sext, and Hu.[19]

Antibodies

Anti-M and anti-N antibodies are usually cold-reactive, clinically insignificant antibodies that are naturally occurring; that is, present in persons who have not been previously transfused

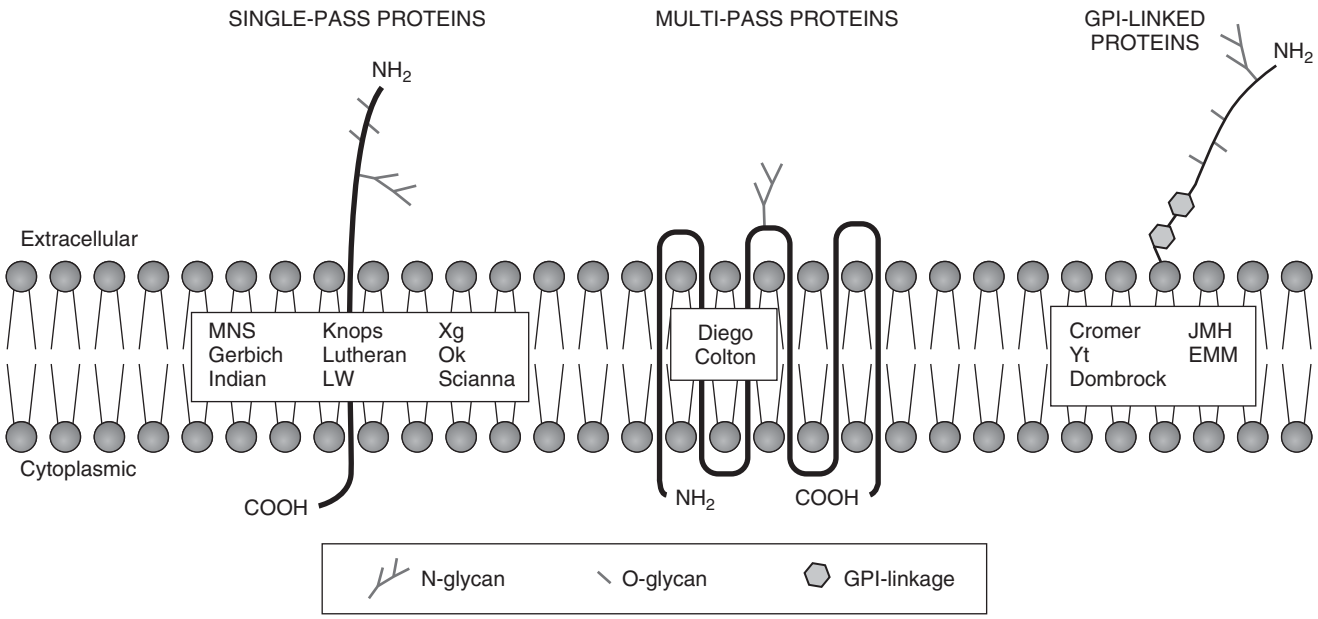

Figure 8–1 Diagram of the red blood cell membrane illustrates the type of membrane components that carry the blood group antigens described herein. The figure does not show components carrying Chido/Rodgers antigens, because they are not integral membrane components, or most of the components carrying the blood group collections, and high- and low-incidence antigens, because their structure is unknown.

Table 8–1 **Incidence of Various MNS Phenotypes**

	Percentage	
Phenotype	**Whites**	**Blacks**
M+N–S+s–	6	2
M+N–S+s+	14	7
M+N–S–s+	10	16
M+N+S+s–	4	2
M+N+S+s+	22	13
M+N+S–s+	23	33
M–N+S+s–	1	2
M–N+S+s+	6	5
M–N+S–s+	15	19
M+N–S–s–	0	0.4
M+N+S–s–	0	0.4
M–N+S–s–	0	0.7

or pregnant. Anti-M can be immunoglobulin M (IgM) or IgG (mostly cold-reactive), but anti-N are mostly IgM and rarely IgG. Reactivity of anti-M is often enhanced by acidification of the serum, whereas anti-N are more specific at alkaline pH. Technical problems with these antibodies can usually be avoided if the test is performed strictly at 37°C.

Anti-M is more common than anti-N. Anti-M is common in antenatal patients (even when the fetus is M-negative); however, there are few reports of potent IgG anti-M that is active at 37°C and causes HDN. If a rare example of anti-M, reactive at 37°C, is identified, the patient should be transfused with M-negative blood as a precaution. Anti-N is not known to cause hemolytic transfusion reactions or HDN; therefore, selection of N-negative blood for transfusion of patients with the antibody is not necessary. It should be noted, however, that rare examples of anti-N, which are compatible only with N–U–RBCs, may be clinically significant.[20]

In contrast, antibodies to S, s, and U usually occur after stimulation and are capable of causing hemolytic transfusion reactions and HDN.[21] Antigen-negative blood should be selected for transfusion of persons with these antibodies. Most anti-S and anti-s are IgG antibodies shown to be reactive on the indirect antiglobulin test (IAT). However, IgM anti-S exist and are more common than IgM anti-s. Anti-U is IgG, reacts on the IAT, and can cause severe transfusion reactions or severe HDN.

Human sera often contain antibodies against one or more of the MNS system antigens, particularly antibodies directed at the low-incidence antigens, but the source of the stimulation is usually unknown.[21] These antibody specificities are often not separable by absorption or elution, and they recognize amino acid sequences common to more than one antigenic determinant. Antibodies to low-incidence antigens in the MNS system may be IgG or IgM. The corresponding antigens are well-developed on RBCs from newborn babies, and the antibodies may cause HDN. Almost all random donors are compatible, and there is no difficulty in finding blood for transfusion.

Anti-En^a is an umbrella term for immune antibodies that react with high-incidence determinants along GPA. The reactivity of anti-En^a in serologic tests using protease-treated RBCs depends on the location of the specific antigen on GPA. En^a antibodies are usually IgG, react on the IAT, and may cause transfusion reactions or HDN.[7,20] It is difficult, if not impossible, to find compatible donor blood for patients with these antibodies. Siblings of such patients should be tested for compatibility, and patients should be urged to donate blood for long-term cryogenic storage when their clinical state permits.

Expression

Antigens in the MNS system are expressed on RBCs from newborns. GPA and GPB are expressed in renal endothelium and epithelium.[22,23] Expression of GPA and GPB in erythroid

tissues occurs early in erythroid differentiation, but the associated antigens are detectable only later in erythroid development.[8,24]

Evolution

Glycophorin A and the MN antigens are found on RBCs of all anthropoid apes (chimpanzee, gorillas, orangutan, and gibbon) and Old World monkeys, but GPB has been found only in humans and the anthropoid apes. Only humans have S and s antigens. The glycophorin gene duplication that generated GPA and GPB is not present in gibbons or orangutans and probably occurred in a common ancestor of anthropoid apes.[25]

Function

Glycophorin A (also known as *membrane inhibitor of reactive lysis type II,* MIRL II) may function as a complement regulator[26] and is a receptor for bacteria, viruses, and *Plasmodium falciparum* malaria parasites.[9,27,28] It is a chaperone for band 3 transport to the RBC membrane and is the major component contributing to the negatively charged RBC glycocalyx,[8,29] which may contribute antiadhesion properties.[30–32] As single-pass membrane proteins, the glycophorins have been considered candidate mediators of transmembrane signaling in RBCs.[33] Rare GPA and GPB null phenotypes—En(a−), U−, and M^kM^k—have RBCs that survive normally; people with these rare phenotypes have no apparent health defects.[8]

THE LUTHERAN SYSTEM (ISBT SYSTEM 005)

History

Anti-Lu^a was first found in 1946 in the serum of a patient who had received multiple transfusions, and it agglutinated 8% of random samples.[34] The system should have been named *Lutteran*, after the name of the donor of the Lu(a+) RBCs; however, the handwritten label on the blood sample from the original donor was misread.

Gene, Protein, and Antigens

Lutheran (LU), along with *Secretor,* provided the first example of autosomal linkage in humans, the first example of autosomal crossing over, and the first indication that crossing over in humans is more common in females than in males.[35,36]

The *LU* gene, located on chromosome 19q13.2–q13.3, consists of 15 exons distributed over approximately 12 kb of DNA. *LU* encodes the Lutheran (Lu) glycoprotein and a spliced form of the glycoprotein, basal cell adhesion molecule (B-CAM). Lu glycoprotein passes through the RBC membrane once with the N terminus oriented to the extracellular surface, and the cytoplasmic region of Lutheran glycoprotein interacts with the membrane cytoskeleton.[37] The protein is predicted to have five disulfide-bonded, extracellular, Ig superfamily (IgSF) domains (two variable-region and three constant-region sets).[38] The Lu glycoprotein has five sites for N-glycans and is O-glycosylated and has an approximate M_r of 85,000 on SDS-PAGE; there are 1500 to 4000 copies per RBC.[39,40] The minor isoform (B-CAM) has an approximate M_r of 78,000, because it lacks the cytoplasmic tail and has an increased expression on epithelial cancer cells.[38,41]

The Lutheran system consists of four pairs of antigens (Lu^a/Lu^b, Lu6/Lu9, Lu8/Lu14, Au^a/Au^b) and 10 independent antigens. The Lu^a antigen is present in 5% of blacks and 8% of whites, and the antithetical antigen, Lu^b, is present in more than 99% of random blood samples.[7] Only Lu9 and Lu14 are low-incidence antigens; the others are either polymorphic (Lu^a, Au^a, and Au^b) or of high incidence (Lu^b, Lu3, Lu4, Lu5, Lu6, Lu7, Lu8, Lu11, Lu12, Lu13, Lu16, Lu17, and Lu20). The molecular basis of Lu^a/Lu^b is His77Arg, and that of Au^a/Au^b is Thr539Ala.[42,43]

The Lu^a and Lu^b antigens, and most of the other Lutheran antigens, are resistant to treatment by papain, ficin, sialidase, and low concentrations (50 mM) of dithiothreitol (DTT), and are sensitive to treatment by trypsin and α-chymotrypsin.[7]

Lutheran-null phenotypes have three genetic backgrounds: homozygozity for a recessive gene mutation *Lu,* a dominant suppressor gene *In(Lu)* (inhibitor of Lutheran), and an X-linked recessive gene *XS*[44] (Table 8–3). Only the autosomal recessive Lu(a−b−) is a true null phenotype;

Table 8–3 **Characteristics of Lu(a–b–) Phenotypes**

Lu(a–b–) Phenotype	Lutheran Antigens	Make Anti-Lu3	CD44	CDw75	I/i Antigen
Recessive	Absent	Yes	Normal	Normal	Normal/normal
Dominant	Weak	No	Weak (25%–39% of normal)	Strong	Normal/weak
X-linked	Weak	No	Normal	Absent	Weak/strong

weak expression of Lutheran antigens are found on RBCs of the two other types. The original Lu(a−b−) phenotype was discovered by the proposita herself when her own RBCs were not agglutinated by anti-Lu^a or anti-Lu^b.[44] Later, it was shown that these RBCs had weak expression of Lutheran antigens and that the phenotype was inherited in a dominant manner and unlinked to *LU*.[44] The presence of an inhibitor gene, *In(Lu),*[45] was proposed. *In(Lu)* is also associated with reduced expression of CD44,[46,47] and weak expression of P_1, AnWj, In^b, i, and MER2 blood group antigens.[48]

Antibodies

Antibodies in this system are rarely encountered because the antigens are not highly immunogenic (see Table 5–5).[21] Anti-Lu^a are usually IgG and reactive on the IAT, but they may be IgM and may directly agglutinate Lu(a+) RBCs, giving characteristic stringy agglutinates surrounded by unagglutinated RBCs. Anti-Lu^a has not been implicated in transfusion reactions and has rarely caused mild HDN. Anti-Au^a and anti-Au^b are rare, usually found in sera that contain other antibodies. They are IgG, react on the IAT, and can cause mild transfusion reactions, but neither has caused HDN.

Several Lutheran antibodies are directed at antigens of high incidence; the one most frequently encountered is anti-Lu^b. Anti-Lu^b are IgG and react by the IAT but can occasionally be IgM. Anti-Lu^b can cause mild transfusion reactions and has rarely caused mild HDN. Lu(b−) blood should be used for transfusion, but only about 1 in 500 donors are Lu(b−). Anti-Lu3 is found only in the serum of immunized people of the rare recessive Lu(a−b−) phenotype. The antibody is usually IgG, is reactive on the IAT, and may cause a delayed transfusion reaction or HDN. Blood with the Lu(a−b−) phenotype should be used for transfusion of patients with these antibodies.

Antibodies to other high-incidence Lutheran antigens, usually weak IgG antibodies, have not been reported to cause HDN. With the exception of one example of anti-Lu6, which was shown to destroy transfused Lu6 RBCs, these specificities have not caused transfusion reactions. If a patient has formed a Lutheran antibody directed at a high-incidence antigen, it is important to test for compatible siblings and encourage the patient to donate blood for long-term storage when clinical status permits. Anti-Lu9 and anti-Lu14 define low-incidence antigens that have not been reported to cause transfusion reactions or HDN.[7] Most randomly collected blood is antigen negative and compatible.

Expression

Lutheran antigens are expressed weakly on cord RBCs. The antigens are present in various tissues, including brain, heart, kidney, liver, lung, pancreas, placenta, and skeletal muscle.[38]

Lutheran glycoprotein is expressed late during erythroid differentiation and may play a role in mediating erythroblast–extracellular matrix interactions in the marrow and reticulocyte release into the circulation.[33]

Function

Lutheran blood group protein and B-CAM bind laminin, a major component of basement membranes.[49] The cytoplasmic domain interacts with the erythroid skeleton through spectrin binding,[37,50] and the nature of the extracellular and cytoplasmic domains suggests receptor and signal transduction functions. On RBCs, Lutheran glycoprotein may be involved in the adherence of RBCs to vascular endothelial cells and in the vaso-occlusion that is characteristic of sickle cell disease.[51] RBCs from patients with sickle cell disease express approximately 1½ times more Lutheran glycoprotein than do normal RBCs, and have a proportional increase in binding to laminin.[52] Lutheran is phosphorylated in sickle cells, and phosphorylation has been shown to regulate the adhesion to laminin.[53] Although the function of the Lutheran glycoprotein is not fully defined, its involvement in cell-to-cell and cell-to-substrate adhesion is probable.

DIEGO SYSTEM (ISBT SYSTEM 010)

History

The Diego blood group system was named after the producer of the first example of anti-Di^a. The antibody, which had caused HDN in a Venezuelan baby, was reported in detail in 1955. Anti-Di^b was described in 1967, and for many years, the system consisted of two antithetical antigens, Di^a and Di^b.[20] The finding that Di^a and Di^b are carried on band 3, the anion exchanger (AE1),[54,55] was the beginning of the expansion of the Diego system. In 1995, Bruce and colleagues[55,56] located the Wr^a and Wr^b antigens on band 3. Since then, many low-incidence antigens have been assigned to this system, which now consists of 18 antigens.[57–59]

Gene, Protein, and Antigens

The gene encoding band 3 and the Diego antigens, *SLC4A1* (solute carrier family 4, anion exchanger member 1; *DI*; *AE1*; *EPB-3*), consists of 20 exons distributed over 18 kb of DNA and is located on chromosome 17q12–q21.[60,61] There are more than 1 million copies of band 3 in the RBC membrane, making it the most abundant integral RBC protein. The glycoprotein passes through the RBC membrane multiple times and has both the N terminus and the C terminus oriented to the cytoplasm. Band 3 has one large N-glycan, on the fourth extracellular loop, with repeating lactosaminyl groups that accounts for the broad banding pattern of approximate M_r 95,000 to 105,000 on SDS-PAGE. The N-glycan of band 3 carries over half of the red cell A, B, H, I, and i blood group activity.[62]

The Di^a/Di^b polymorphism is located on the last extracellular loop and is defined by Pro854 (Di^b) or Leu854 (Di^a).[55] The Di^a antigen is rare in most populations but is polymorphic in people of Mongoloid ancestry. The incidence in South American Indians may be as high as 54%, and 10% to 12% of Native Americans are Di(a+).[63] The incidence of Di^b is generally greater than 99.9%; however, the incidence of Di^b among Native Americans is reduced to 96% and is likely to be lower in those populations with a high incidence of Di^a. The Wr^a/Wr^b polymorphism is located on the fourth extracellular loop, close to the insertion into the RBC membrane, and is defined by Lys658 (Wr^b) or Glu658 (Wr^a); however, for expression, the Wr^b antigen also requires the presence of normal GPA.[56,64,65]

The other antigens in the Diego system—Wd^a, Rb^a, WARR, ELO, Wu, Bp^a, Mo^a, Hg^a, Vg^a, Sw^a, BOW, NFLD, Jn^a, and KREP[57]—are of low incidence and are each associated with a single point mutation.[58,59] The antigens are resistant to treatment of RBCs by proteolytic enzymes, sialidase, DTT, chloroquine, and acid.[7]

Antibodies

Diego antibodies are usually IgG that react on the IAT and do not bind complement. These antibodies have caused transfusion reactions (usually delayed) and HDN.[7,66]

Expression

Diego antigens are expressed on RBCs of newborns. Band 3, in addition to its presence on RBCs, is present in the intercalated cells of the distal and collecting tubules of the kidney and on granulocytes.[62]

Evolution

A variant form of band 3, Memphis I (56Glu), has a faster migration on SDS-PAGE than the more common form (56Lys). Evidence suggests that the primordial gene encodes 56Glu and that 56Lys is the result of a more recent mutation.[67]

Function

Band 3 is the major anion $HCO_3^-Cl^-$ exchanger in RBC membrane. This function is critical for RBC CO_2 uptake from the tissues and release of CO_2 in the lungs. In addition, band 3 has an important structural role in the RBC membrane through the interaction of its N-terminal domain with ankyrin, band 4.2, and band 4.1 in the membrane skeleton.[61,62] An altered form of band 3, with a deletion of amino acid residues 400 through 408, is present in ovalocytes of Southeast Asian people and causes the RBCs to be rigid.[68–70] Numerous mutations exist in the predicted cytoplasmic or transmembrane domains of band 3 and give rise to hereditary spherocytosis, congenital acanthocytosis, and distal renal tubular acidosis.[59,71]

Yt BLOOD GROUP SYSTEM (ISBT SYSTEM 011)

History

The Yt system was named in 1956,[72] the last letter of the antibody producer's name, Cartwright, being used because the other letters of the name were already in use. The logic was that if all the other letters had been used, "Why not t?," or "Why t?" (Yt) (M. Pickles, personal communication, 1999).

Gene, Protein, and Antigens

ACHE encodes acetylcholinesterase (AChE), a glycosylphosphatidylinositol-linked (GPI-linked) glycoprotein that exists as a dimer in the RBC membrane.[73] The gene is located on chromosome 7q22 and consists of six exons.[7,74,75] Alternative splicing results in different domains at the C terminus of AChE. AChE glycoprotein has N-glycans and O-glycans and an approximate M_r of 160,000 (72,000 monomer) on SDS-PAGE; there are 10,000 copies per RBC.[7,73]

Yt^a and Yt^b antigens are antithetical and a consequence of an amino acid substitution on AChE, His353Asn (originally numbered 322).[76] Yt^a occurs with an incidence of more than 99% in random blood samples. Yt^b has an incidence of 8% in most populations, but of 20% or higher in Israelis.[77]

The antigens are sensitive to treatment of RBCs by papain, ficin, α-chymotrypsin, and DTT but resistant to treatment by trypsin, sialidase, chloroquine, and acid.[7]

Antibodies

Yt antibodies usually are IgG, are reactive on IAT, and do not bind complement. These antibodies have caused delayed transfusion reactions but not HDN.

Expression

Acetylcholinesterase is expressed on hematopoietic and innervated tissue (including brain and muscle).[78,79] The antigens are expressed weakly on RBCs of newborns and are absent from RBCs of people with paroxysmal nocturnal hemoglobinuria (PNH) III.[80]

Evolution

A form of AChE has been found in the electric fish *Torpedo californica*.[81]

Function

Acetylcholinesterase is a well-characterized enzyme that hydrolyzes acetylcholine and is an essential component of cholinergic neurotransmission.[78] The role of AChE in RBCs is unknown,[82] but the molecule is enzymatically active.[73]

Xg BLOOD GROUP SYSTEM (ISBT SYSTEM 012)

History

Anti-Xg^a, discovered in 1962, detects an antigen encoded by a locus on the X chromosome. The "X" was used because of the association with the X chromosome, and the g stood for Grand Rapids, Michigan, the home of the male patient who had received multiple transfusions and who made the first anti-Xg^a.[83] Xg^a has been useful in linkage studies involving the X chromosome and in sex chromosome aneuploidy, in which an abnormal number of X chromosomes occurs.[63]

Gene, Protein, and Antigens

The gene encoding Xg^a is located at Xp22.32; it is not subject to X inactivation due to the expression of a duplicate gene, *MIC2,* located telomeric and in the pseudoautosomal region of the X chromosome. The first three of the ten exons of *XG* are in the pseudoautosomal region of the X chromosome; exons 4 through 10 are X-specific; hence the alternative name *PBDX* (pseudoautosomal boundary divided on X) for *XG*.[84]

The Xg glycoprotein passes through the membrane once with the amino terminus to the outside of the RBC. N-glycans are not present, but there are 16 potential sites for O-glycans, and the protein has numerous proline residues. On SDS-PAGE, Xg has a M_r of 22,000 to 29,000, and there are approximately 9000 copies per RBC.[7] The difference between Xg(a+) and Xg(a−) is the level of Xg^a antigen on the RBC, rather than a different gene product.[33,85] Xg glycoprotein has 48% identity with the CD99 glycoprotein.[84] Because an altered form of CD99 in a person with alloanti-CD99 has been described, the ISBT Working Party assigned CD99 the number XG2 (012.002).[86]

The incidence of Xg^a differs in males (65.6%) and females (88.7%), and there is a phenotypic association between the expression of Xg^a and CD99 (formerly known as 12E7 antigen) (Table 8–4). The Xg^a antigen is sensitive to treatment of RBCs by proteolytic enzymes but resistant to treatment by sialidase and DTT.[7]

Antibodies

Anti-Xg^a is usually IgG that is reactive on the IAT and may bind complement. Some anti-Xg^a are apparently naturally occurring. These antibodies have not caused transfusion reactions or HDN.[7]

Expression

The antigen is expressed weakly on RBCs of newborns. Xg is expressed on fibroblasts as well as on fetal liver, spleen, thymus, and adrenal glands and on adult bone marrow.[84]

Evolution

Xg^a is on the RBCs of some gibbons *(Hylobates lar)*. RBCs of other great apes, various monkeys (including baboons), mice, and dogs are Xg(a−).[63]

Function

The role of the protein carrying Xg^a in RBCs is unknown, but it is thought to be important in hematopoietic cell differentiation. Xg is homologous with CD99.[87] CD99 has been implicated in cell-to-cell adhesion events,[85,88] activates a caspase-independent apoptosis pathway in T cells,[89] and is expressed on human RBCs, all leukocyte lineages, and all other human tissue tested.

Table 8–4 **Phenotype Relationship of Xg^a and 12E7[CD99] Antigens**

Sex	Xg^a	CD99 Expression
Male	Positive	High
	Negative	High or low
Female	Positive	High
	Weak positive	High
	Negative	Low

SCIANNA BLOOD GROUP SYSTEM (ISBT SYSTEM 013)

History

The Scianna system was named after the first antibody producer. The first example of anti-Sc1 (initially called anti-Sm) was reported in 1962. The antithetical antigen, Sc2, was originally called Bu^a.[63] In 1974 the relationship of these antigens was recognized and they were renamed Scianna.[90]

Gene, Protein, and Antigens

Scianna is the last of the blood group systems carried on a membrane protein to be elucidated. The gene encoding Sc antigens was known to be located on chromosome 1p36.2–p22.1, but only recently was it shown that the antigens are expressed by the red cell adhesion protein, erythrocyte membrane-associated protein (ERMAP).[91,92] The ERMAP glycoprotein has at least one N-glycan, one or more disulfide bonds, and an approximate M_r of 60,000 to 68,000 on SDS-PAGE.[93] The glycoprotein is predicted to have one extracellular transmembrane immunoglobulin-like domain.

The high-incidence antigen Sc1 (incidence ≈99.9%) is antithetical to the low-incidence antigen Sc2 (1%). Sc1, Sc2, and the high-incidence antigen Sc3 are lacking on RBCs of the very rare null phenotype Sc:−1,−2,−3. The low frequency antigen Rd (Radin) is also carried on the ERMAP protein and is part of the Scianna blood group system.[92] The antigens are resistant to treatment of RBCs by papain, ficin, trypsin, α-chymotrypsin, sialidase, acid, and 50 mM of DTT, but sensitive to treatment of RBCs with 200 mM of DTT.[7]

Antibodies

Scianna antibodies are usually IgG reactive on the IAT, and some bind complement. These antibodies have not caused transfusion reactions, but have caused a positive direct antiglobulin test (DAT) requiring transfusion support in a newborn.[94] Several examples of autoanti-Sc1 have been reported, some reactive in tests using patient serum but not plasma. Autoanti-Sc3-like antibodies have been described in one patient with lymphoma and in one patient with Hodgkin's disease whose RBCs had suppressed Sc antigens.[7]

Expression

The Sc antigens are erythrocyte specific and are expressed on RBCs of newborns.[94] ERMAP is expressed throughout erythropoiesis.[91]

Function

The function of ERMAP is not known. In addition to an extracellular transmembrane immunoglobulin-like domain, the intracellular region has multiple kinase-dependent phosphorylation consensus motifs, suggesting it may be a receptor/signal transduction molecule.[95] Individuals with the Sc:−1,−2 null phenotype appear to be healthy.

DOMBROCK BLOOD GROUP SYSTEM (ISBT SYSTEM 014)

History

The first antibody of the Dombrock system, anti-Do^a, was identified in 1965 in the serum of Mrs. Dombrock. Anti-Do^b was found in 1973. In 1995, it was realized that the Gregory-negative phenotype was the null of the Dombrock system.[96]

Gene, Protein, and Antigens

The Dombrock antigens are carried on a mono-ADP-ribosyltransferase (ART4), encoded by the *DO* gene.[97] The gene, located at chromosome 12p13.2–p12.1,[98] is composed of three exons distributed over 14 kb.[97,99,100]

The glycoprotein has an approximate M_r of 47,000 to 58,000 on SDS-PAGE and is attached to the RBC membrane via a GPI anchor.[80] The number of copies per RBC is not known.

The incidence of each Dombrock phenotype and the association of Gregory (Gy^a), Holley (Hy), and Joseph (Jo^a) phenotypes with Do^a and Do^b are summarized in Table 8–5. Although three nucleotide substitutions are associated with the various *DO* alleles, the amino acid substitutions associated with expression of the antigens are as follows: Do^a/Do^b, Asn265Asp;[97] Hy+/Hy−, Gly108Val; and Jo(a+)/Jo(a−), Thr117Ile.[101] The Gy(a−) phenotype arises from different molecular backgrounds—donor and acceptor splice site mutations, nonsense mutation, and deletion of eight nucleotides.[102–104] The antigens are resistant to treatment of RBCs by ficin, papain, sialidase, 50 mM of DTT, and acid, weakened by treatment with α-chymotrypsin, and sensitive to treatment by trypsin and 200 mM of DTT.[7]

Antibodies

Do^a and Do^b antigens are poor immunogens, and anti-Do^a and anti-Do^b are rarely found as single specificities. In contrast, Gy^a is immunogenic. Antibodies in the Do system are usually IgG reactive on the IAT and do not bind complement. These antibodies have caused delayed transfusion reactions and a positive DAT result, but no clinical HDN. Anti-Do^a and anti-Do^b are notorious for disappearing in vivo.[66]

Expression

The Dombrock antigens are expressed on RBCs of newborns. They are absent from PNH III RBCs.[80]

Function

The function of Dombrock glycoprotein is not known. Although the enzyme ART4 acts as a regulator of protein function through post-translational modification by addition of adenosine diphosphate (ADP)-ribose to a target molecule, the Dombrock glycoprotein has not been shown to have enzymatic activity.[33]

COLTON BLOOD GROUP SYSTEM (ISBT SYSTEM 015)

History

The Colton system, named after the first producer of anti-Co^a, was reported in 1967. The association of this blood group system with a 28-kDa integral membrane protein (CHIP-28) led to the discovery of the first water channel protein.

Gene, Protein, and Antigens

The Colton blood group antigens are carried on the water transport protein, known as *channel-forming integral protein* (CHIP-1) or *aquaporin 1* (AQP-1).[105] The gene (*AQP1* or *CO*) encoding the Colton glycoprotein is on chromosome 7q14 and comprises four exons distributed over 17 kb.

The glycoprotein passes through the RBC membrane multiple times, has cytoplasmic N and C termini, and is N-glycosylated. The N-glycan carries A, B, H, I, and i blood group activity. On SDS-PAGE, the Colton glycoprotein has an approximate M_r of 28,000 in the unglycosylated form and 40,000 to 60,000 in the glycosylated form.[105] There are 120,000 to 160,000 molecules of AQP-1 arranged in tetramers on the RBC membrane.[7]

The Colton blood group system consists of three antigens: Co^a, Co^b, and Co3. Co^a has an incidence of 99.9%, its antithetical antigen Co^b has an incidence of 10%, and Co3 is present on all RBCs except those of the very rare null phenotype Co(a−b−). Only four Co(a−b−) propositi are reported, all of which were found because of the presence of anti-Co3 in their sera. The Co(a−b−) phenotype arises from various molecular backgrounds, including exon deletion, missense mutations, and a single nucleotide insertion.[106–108]

The amino acid substitution responsible for the Co^a/Co^b polymorphism is on the first extracellular loop of AQP-1 and results from an Ala45Val substitution.[109] The antigens are resistant to treatment of RBCs by proteases, sialidase, DTT, and acid.[7]

Antibodies

Antibodies in the Co system are usually IgG reactive on the IAT, and some bind complement. The antibodies have caused delayed transfusion reactions and HDN.[66]

Table 8–5 **Dombrock Phenotypes and Their Incidences (in Percentage)**

Phenotype	Do^a	Do^b	Gy^a	Hy	Jo^a	Whites	Blacks
Do(a+b−)	+	0	+	+	+	18	11
Do(a+b+)	+	+	+	+	+	49	44
Do(a−b+)	0	+	+	+	+	33	45
Gy(a−)	0	0	0	0	0	Rare	0
Hy−	0	Weak	Weak	0	0	0	Rare
Jo(a−)	Weak	0/Weak	+	Weak	0	0	Rare

Expression

The Co antigens are expressed on RBCs of newborns. AQP-1 is strongly expressed in the kidney on the apical surface of proximal tubules, the basolateral membrane subpopulation of collecting ducts in the cortex, and the descending tubules in the medulla, as well as on liver bile ducts, gallbladder, brain, lung, eye epithelium, cornea, lens, choroid plexus, hepatobiliary epithelia, and capillary endothelium.[105,110]

Evolution

AQP-1 is a member of a large family of proteins that are involved in water transport and are found in all domains of life.[111]

Function

The function of AQP-1 is to transport water, and it accounts for 80% of water reabsorption in kidneys. Defective urine-concentrating ability[112] and decreased pulmonary vascular permeability[113] are seen with complete AQP-1 deficiency. The function of AQP-1 in RBCs may be to rehydrate rapidly after shrinking in the hypertonic environment of the renal medulla.[114] Apparently healthy propositi with the Co(a−b−) phenotype and AQP-1 deficiency have RBCs with an 80% reduction in the ability to transport water.[96] The residual water transport in these RBCs may be through another member of the water channel protein family, AQP-3, which transports water, glycerol, and urea[115] and carries the blood group antigen GIL.[116]

LW BLOOD GROUP SYSTEM (ISBT SYSTEM 016)

History

In 1940, Landsteiner and Wiener[117] produced an antibody by injecting rabbits and guinea pigs with RBCs from rhesus monkeys; they named the antibody Rh after rhesus monkey. A few years later, it was shown that the animal anti-Rh were different from the human Rh antibody (i.e., anti-D); thus, the animal anti-Rh was renamed anti-LW in honor of Landsteiner and Wiener.

The historical terminology LW_1, LW_2, LW_3, and LW_4 to describe phenotypes was changed when the antithetical relationship of the antigen defined by anti-Ne^a (now called anti-LW^b) and that defined by anti-LW made by LW_3 people (now called anti-LW^a) was recognized.[7,118]

Gene, Protein, and Antigens

The LW glycoprotein, also called *intracellular adhesion molecule 4* (ICAM-4), is a member of the IgSF.[119] The gene *(LW)* encoding the LW glycoprotein consists of three exons distributed over 2.65 kb of DNA on chromosome 19.

The LW glycoprotein passes through the RBC membrane once, and the N-terminal extracellular region is organized into two IgSF domains.[119] LW glycoprotein has an approximate M_r of 37,000 to 43,000 on SDS-PAGE, has three pairs of cysteine residues and four potential N-glycan sites, and is O-glycosylated.

LW^a is a common antigen, whereas LW^b has an incidence of less than 1% in most Europeans (but is found in 6% of Finns and in 8% of Estonians). RBCs with the Rh-null phenotype lack LW antigens and type LW(a−b−). The LW^{ab} antigen was originally defined by the alloantibody made by the only genetically LW(a−b−) person. There is a phenotypic relationship between LW and the D antigen of the Rh system; D-positive RBCs have stronger expression of LW antigen than D-negative RBCs, and the expression of LW is stronger on cord RBCs than on RBCs from adults.[120]

The LW^a/LW^b polymorphism is due to the amino acid substitution Gln70Arg.[121] LW antigens require intramolecular disulfide bonds and the presence of divalent cations, notably Mg^{2+}, for expression.[122] The antigens are resistant to treatment of RBCs by ficin, papain, trypsin, α-chymotrypsin (but may be weakened), sialidase, and acid; they are sensitive to treatment of RBCs by pronase and DTT. These features are helpful in the differentiation of anti-LW from anti-D, because the D antigen is resistant to pronase and DTT treatment.[7]

The LW gene of the only genetic LW(a−b−) person has a 10-deletion and a premature stop codon in the first exon.[123]

Transient loss of LW antigens from the RBC has been described in pregnancy and in patients with diseases, particularly Hodgkin's disease, lymphoma, leukemia, sarcoma, and other forms of malignancy. Such loss of LW antigens is usually associated with the production of LW antibodies.[124]

Antibodies

Antibodies in the LW system are IgM and IgG that are reactive at room temperature or on the IAT and do not bind complement. They have occasionally caused mild delayed transfusion reactions and mild HDN. Autoanti-LW are common in patients with transient depression of LW antigens and can appear to be alloantibodies.[66]

Expression

The LW antigens are expressed on RBCs of newborns in equal amounts regardless of D type. In contrast, D-positive RBCs of adults express more LW than D-negative RBCs. LW glycoprotein appears early in erythropoiesis, before GPA.

Evolution

LW antigen has been detected on RBCs of all primate species tested, including chimpanzee, gorilla, orangutan, and a variety of monkey species.

Function

LW glycoprotein has homology to ICAMs, and interacts with integrins LFA1 (CD11/CD18),[125] α4β1, and αV[126] and also binds platelet-specific integrin, αIIbβ3.[127] The significance of these observations is not yet known, but LW glycoprotein may function in erythroblast–macrophage interactions in erythroblastic islands.[128] The proband and her brother who have the rare inherited LW-null phenotype do not have an apparent hematologic defect.

CHIDO-RODGERS BLOOD GROUP SYSTEM (ISBT SYSTEM 017)

History

Antigens in the Chido-Rodgers system were named after the first antibody producers, Ch for *Ch*ido and Rg for *R*odgers.

Anti-Ch was first described in 1967, and when anti-Rg was reported in 1976, there were obvious similarities between them. Although the Ch and Rg antigens are readily detected on RBCs and were given blood group system status, later work revealed that Ch and Rg antigens are located on the fourth component of complement (C4), which becomes bound to RBCs from the plasma.

Gene, Protein, and Antigens

In complement activation through the classical pathway, C4 becomes bound to the RBC membrane and undergoes further cleavage; ultimately, a tryptic fragment, C4d, remains on the RBC. This C4d glycoprotein carries the Chido-Rodgers blood group antigens. Electrophoresis identified the following two isoforms of C4: C4B, the slower-migrating molecule, expresses Ch antigens, and C4A, the faster molecule, expresses Rg antigens.[129] C4A and C4B are not the products of alleles, but are encoded by genes at two very closely linked loci located at chromosome 6p21.3. Silent alleles are relatively common at each locus. *C4A* and *C4B* have been cloned, and each consists of 41 exons and is 22 kb long, although a shorter form of *C4B* exists. C4A and C4B glycoproteins are 99% identical in their amino acid sequences.

The Chido-Rodgers blood group system contains nine antigens. Some or all of the antigens may be expressed by a particular phenotype. Ch1 to Ch6, Rg1, and Rg2 have frequencies greater than 90%. The WH antigen has an incidence of about 15%. The various antigens are associated with amino acid differences in eight residues.[130,131] The antigens are stable in stored serum or plasma, and the phenotypes of this system are most accurately defined in plasma by hemagglutination inhibition tests.[7]

The antigens are sensitive to treatment of RBCs by proteases and resistant to treatment by sialidase, DTT, and acid. RBCs coated with C4 (+C3) through the use of low-ionic strength 10% sucrose solution give enhanced reactivity with anti-Ch and anti-Rg; this feature has been used to aid identification of antibodies.[7]

Antibodies

Antibodies in the Chido-Rodgers system are usually IgG reacting by the IAT, do not activate complement, and are considered benign and nebulous. There can be considerable variation in the reaction strength obtained with different RBC samples. Although these antibodies do not generally cause transfusion reactions, they have caused anaphylactic reactions.[132] The antibodies have not caused HDN. Anti-Ch and anti-Rg are neutralized in the test tube or in the circulation by plasma from Ch-positive and Rg-positive persons, respectively.

Expression

Chido-Rodgers antigens are absent or weakly expressed on RBCs of newborns. They are weakly expressed on RBCs of some people with the dominant Lu(a−b−) phenotype and on GPA-deficient (i.e., sialidase-deficient) RBCs. Indeed, it is not possible to coat sialidase-deficient RBCs with C4 in vitro through the 10% sucrose technique.[133]

Function

C4A binds preferentially to proteins and C4B to carbohydrates. C4B binds more effectively to the RBC surface (through sialic acid) and thus is more effective at promoting hemolysis. A single amino acid substitution, Asp1106His, converts the functional activity of C4B to C4A, whereas Cys1102Ser affects hemolytic activity and IgG binding.[134]

Inherited low levels of C4 may be a predisposing factor for diseases such as insulin-dependent diabetes and autoimmune chronic active hepatitis. Specific C4 allotypes and null genes have been associated with numerous autoimmune disorders, including Graves' disease and rheumatoid arthritis. Lack of C4B (Ch−) bestows greater susceptibility to bacterial meningitis on children. Lack of C4A (Rg−) results in a predisposition for systemic lupus erythematosus (SLE).[134]

GERBICH BLOOD GROUP SYSTEM (ISBT SYSTEM 020)

History

The Gerbich system was named in 1960 after Mrs. Gerbich, the first antibody producer.

Gene, Protein, and Antigens

The three high-incidence antigens (Ge2, Ge3, and Ge4) and four low-incidence antigens (Wb, Ls^a, An^a, and Dh^a) of the Gerbich blood group system are carried on GPC, GPD, or both. The two glycoproteins are products of the *GYPC* gene.[135] The gene, located at chromosome 2q14–q21, consists of four exons. The smaller GPD polypeptide is generated by the use of alternative translation initiation sites. On SDS-PAGE, GPC has an approximate M_r of 40,000; it has one N-glycan and 13 sites for O-glycans. GPD has an approximate M_r of 30,000, no N-glycan, and 8 sites for O-glycans. There are approximately 135,000 copies of GPC and 50,000 copies of GPD per RBC. GPC and GPD pass through the RBC membrane once with their N terminus oriented to the outside of the membrane.

Ge2 is located on the N terminus of GPD, Ge3 is located between amino acid residues 40 and 50 on GPC and between residues 19 and 28 on GPD, and Ge4 is located at the N terminus of GPC. Of the four low-incidence antigens, three (Wb, An^a, Dh^a) are the result of an amino acid substitution, and one (Ls^a) is created by a novel amino acid sequence derived from a duplication of exon 3 and encoded by nucleotides at the exon 3 to exon 3 junction.[135]

Except in Papua New Guinea, Gerbich-negative RBCs are seldom found. The three Gerbich-negative phenotypes are as follows: Ge:−2,3,4 (the Yus phenotype), Ge:−2,−3,4 (the Gerbich phenotype), and Ge:−2,−3,−4 (the Leach phenotype). The Leach phenotype is the null of the Gerbich system. The PL type (the original propositus) arises from a deletion of exons 3 and 4 of *GYPC*. The LN type is caused by a deletion of nucleotide 134, changing Pro45Arg of GPC, a frameshift mutation, and a premature stop codon. The Gerbich phenotype is due to a deletion of exon 3, and the Yus phenotype is due to a deletion of exon 2 of *GYPC*.[135–139] The Yus and Gerbich phenotypes have been found in diverse populations, but in the Melanesians of Papua New Guinea only the

Gerbich type has been found.[135] The Leach phenotype has been restricted to people of Northern European extraction.

Ge2 and Ge4 are sensitive to treatment of RBCs by ficin, papain, and trypsin; Ge3 is sensitive to trypsin but resistant to ficin and papain; and all antigens are resistant to treatment of RBCs with α-chymotrypsin, DTT, and acid.[7]

Antibodies

The antibodies may be immune or naturally occurring. Most are IgG and are reactive on the IAT, and some of these bind complement; some antibodies may be IgM. Although some antibodies have caused delayed transfusion reactions, others have been benign. Clinical HDN due to these antibodies has not been reported, but the antibodies have been eluted from cord RBCs that tested positive on DAT. Antibodies to the high-incidence Gerbich antigens are rare; the least rare specificity is anti-Ge2, which can be produced by any of the three Gerbich-negative phenotypes. Clinically significant auto-anti-Ge have been reported. Because Ge-negative donors are rare, it is important to test siblings of Ge-negative patients for compatibility, and to urge such patients to donate blood for long-term storage.[66]

Antibodies to low-incidence antigens in the Ge blood group system are rare, and RBCs from almost all random donors are compatible; there is no difficulty in finding blood for transfusion of patients with these antibodies. One brief report implicated anti-Ls^a in HDN,[140] but there are no reports of HDN due to anti-Wb, anti-An^a, or anti-Dh^a.

Expression

Ge antigens are expressed on RBCs of newborns. Gerbich antigens are weak on protein 4.1-deficient RBCs because the membranes of such cells have reduced levels of GPC and GPD. The majority of RBC samples with Leach or Gerbich phenotypes have a weak expression of Kell blood group system antigens. GPC and GPD are expressed on erythroblasts and fetal liver and in several nonerythroid tissues, including kidney, brain cerebellum, and ileum.[7]

Function

Glycophorin C and GPD are possibly involved in RBC membrane integrity via interaction with protein 4.1. Both glycophorins are markedly reduced in protein 4.1-deficient RBCs.[141]

CROMER BLOOD GROUP SYSTEM (ISBT SYSTEM 021)

History

The Cromer system was named after the first antibody producer, Mrs. Cromer. When the antibody was first identified in 1965, it was believed to be anti-Go^b; later, however, it was recognized as a new specificity, and in 1975, it was renamed anti-Cr^a.

Gene, Protein, and Antigens

Blood group antigens in the Cromer system are carried on the complement regulatory protein, decay accelerating factor (DAF, CD55). The *DAF* gene, located at chromosome 1q32, is one of a group of genes known as the regulators of complement activation (RCA) cluster. The gene spans approximately 40 kb and comprises 11 exons.[142] The DAF glycoprotein is arranged into four extracellular short consensus repeat domains, each with about 60 amino acid residues, and is attached to the RBC membrane through GPI linkage. On SDS-PAGE, DAF has an approximate M_r of 64,000 to 73,000 (reduced) and 60,000 to 70,000 (nonreduced). One N-glycan and 15 O-glycans are present on each glycoprotein, and there are 20,000 copies of DAF per RBC.[143]

Cromer is a system of 11 antigens with two sets of antithetical antigens, $Tc^a/Tc^b/Tc^c$ and WES^a/ WES^b. Eight of the antigens (Cr^a, Tc^a, Dr^a, Es^a, IFC, WES^b, UMC, and GUTI) are of high incidence, and three (Tc^b, Tc^c , and WES^a) are of low incidence. These antigens are lacking from the Cromer null phenotype, the Inab phenotype. The amino acids required for expression of all the antigens have been determined; with the exception of Dr^a, all are due to a single amino acid change.[144,145] In the Dr(a−) phenotype, the level of expression of DAF, and therefore of all Cromer system antigens, is greatly reduced. The Cr(a−) phenotype is the least rare of the negative phenotypes, and with the exception of one Spanish-American woman, all people with Cr(a−) RBCs are black. Most of the other phenotypes are exceedingly rare.

Cromer antigens are resistant to treatment of RBCs by ficin, papain, trypsin, 50 mM of DTT, sialidase, and acid, are sensitive to α-chymotrypsin, and are weakened by 200 mM of DTT.[7]

Antibodies

Antibodies in the Cromer system are usually IgG, are reactive on the IAT, and do not bind complement. The antibodies have caused mild delayed transfusion reactions but not HDN. When a patient's antibody is directed at a high-incidence antigen, it is important to test siblings in the quest for compatible blood and to urge the patient to donate blood for long-term storage when clinical status permits.[66]

Expression

The Cromer antigens are expressed on RBCs of newborns. DAF is preferentially expressed on the apical surface of trophoblasts and may protect the conceptus from antibody-mediated hemolysis.[146] DAF is not expressed on RBCs from patients with PNH III. Dr(a−) variant RBCs express inherited Cromer antigens very weakly.

Cromer antigens are present in the plasma and urine of people with the corresponding antigen on their RBCs. This soluble form of the antigens can be used for hemagglutination inhibition tests, although the urine requires prior concentration.[147]

Function

Decay accelerating factor prevents assembly and accelerates the decay of C3 and C5 convertases, decreasing the deposition of C3 on the RBC surface and thereby reducing complement-mediated hemolysis.[143]

Five of the six known people with the Inab phenotype, the null of the system, do not have significant complement-induced lysis in vivo.[148] Protein-losing intestinal disorders have been reported to be associated with Inab, but there

is not a clear disease association.[33] Dr^a is the receptor for uropathogenic *Escherichia coli*.[7]

KNOPS BLOOD GROUP SYSTEM (ISBT SYSTEM 022)

History

The antigens Kn^a, Kn^b, McC^a, Sl^a, and Yk^a had long been grouped together for serologic reasons. In 1991, the Knops blood group system was established when these antigens were shown to be on complement receptor 1 (CR1). The system was named after Mrs. Knops, the first antibody producer.

Gene, Protein, and Antigens

Knops antigens are encoded by various forms of *CR1*.[149] Like *DAF*, the *CR1* gene is located within the RCA cluster on chromosome 1q32. *CR1* has four allotypes: A, B, C, and D. The most common allotypes are A (82%) and B (18%); the other two are rare.

CR1 (CD35) is an unusual protein with 30 short consensus repeat domains. SDS-PAGE reveals the approximate M_r of the CR1 allotypes as follows: 190,000 (C allotype), 220,000 (A allotype), 250,000 (B allotype), and 280,000 (D allotype). Of 20 potential N-glycan sites, only 6 to 8 are usually occupied; there are four cysteine residues. Each RBC contains 20 to 1500 copies of CR1. The CR1 glycoprotein passes through the RBC membrane once with its N terminus toward the extracellular surface. The molecular basis of the McC^a/McC^b polymorphism is associated with a Lys1590Glu missense mutation, and the Sl^a/Vil polymorphism with an Arg1601Gly missense mutation.[150] The antigens are weakened by treatment of RBCs with ficin and papain, are sensitive to treatment by trypsin, α-chymotrypsin, and 200 mM of DTT, and are resistant to sialidase, 50 mM of DTT, and acid.[7]

With the exception of the low-incidence antigen Kn^b, the antigens in this system are fairly common and have a similar prevalence (>90%) in different populations; however, Sl^a is present on RBCs of 98% of whites but on only 60% of blacks.

Typing for Knops system antigens can be challenging because of the low level of expression on the RBCs of some people as well as the lack of potent antisera. Disease processes causing CR1 deficiency and, therefore, weak expression of Knops system antigens can lead to false-negative results. Furthermore, the low level of expression can lead to variable results in tests on different samples from the same patient.

Antibodies

Antibodies in the Knops system are usually IgG and reactive on the IAT, and they do not bind complement. The antibodies do not cause transfusion reactions or HDN; once identified, they can be ignored for clinical purposes. Identification may be complicated by the fluctuation of antigen expression on RBCs. Anti-Kn^a is the most common antibody in white persons, and anti-Sl^a is the most common in black persons.[20]

Expression

The Knops antigens are weakly expressed on RBCs of newborns, RBCs with the dominant Lu(a−b−) phenotype, and RBCs of patients with autoimmune diseases. CR1 is present on B cells, a subset of T cells, monocytes, macrophages, neutrophils, eosinophils, glomerular podocytes, and splenic follicular dendritic cells.[151]

Function

CR1 has an inhibitory effect on complement activation by both the classical and alternative pathways. CR1 binds C3b and C4b, thereby mediating phagocytosis by neutrophils and monocytes. RBC CR1 is important in the processing of immune complexes, binding them for transport to the liver and spleen for removal from the circulation. The presence of CR1 on other blood cells and tissues suggests that it has multiple functions.[149] The CR1 copy number per RBC (and thus antigen strength) is reduced in SLE, cold agglutinin disease, PNH, hemolytic anemia, insulin-dependent diabetes mellitus, acquired immunodeficiency syndrome, some malignant tumors, and any condition associated with increased clearance of immune complexes.

CR1, and the Sl^a antigen in particular, may act as a receptor for the malarial parasite *Plasmodium falciparum*, and thus, the Sl(a−) phenotype may provide selective advantage.[152]

INDIAN BLOOD GROUP SYSTEM (ISBT SYSTEM 023)

History

The In^a antigen, reported in 1973, is on RBCs from 4% of Indians from Bombay. This blood group system was named because of its association with India.

Gene, Protein, and Antigens

In^a and In^b, the antigens of the Indian system, are carried on CD44 (synonyms: In(Lu)-related p80; HUTCH-1; H-CAM; GP90(HERMES), Pgp-1; ECRMIII; Ly-24; p85).[153] The *CD44* gene is located at chromosome 11p13 and consists of at least 19 exons, 10 of which are variably spliced. The CD44 glycoprotein passes through the RBC membrane once, and the extracellular N terminus has six cysteine residues, six N-glycan sites, four chondroitin sulfate sites, and potential sites for O-glycans. There are 2000 to 5000 copies of CD44 per RBC. SDS-PAGE shows that CD44 has an approximate M_r of 80,000 when reduced. The In^a/In^b polymorphism is due to Pro46Arg on CD44.[154] In^b is a common antigen, and In^a is rare in white persons but has an incidence of 4% in Indians, 10% in Iranians, and nearly 12% in Arabs. The antigens are sensitive to treatment of RBCs by proteases and DTT but resistant to treatment with sialidase and acid.[7]

The In(a−b−) phenotype was described in a patient with a novel form of congenital dyserythropoietic anemia (CDA) and CD44 deficiency,[155] but it was not possible to ascertain whether the phenotype was genetically determined or related to the patient's hematologic disorder. The RBCs of the patient also typed AnWj− and Co(a−b−) and had a reduced level of LW^{ab} expression.

Antibodies

Antibodies in the Indian system are usually IgG and reactive on the IAT, and they do not bind complement. Some

antibodies may directly agglutinate RBCs, but the reactivity is greatly enhanced by the IAT. These antibodies have caused decreased RBC survival and a positive DAT result in the neonate but not HDN. A severe, delayed, hemolytic transfusion reaction due to anti-In^b has been reported.[156]

Expression

Indian antigens are weakly expressed on cord RBCs as well as on RBCs from people with the dominant Lu(a−b−) phenotype and from pregnant women. CD44 is expressed on neutrophils, lymphocytes, monocytes, brain, breast, colon epithelium, gastric tissue, heart, kidney, liver, lung, placenta, skin, spleen, thymus, and fibroblasts.

Joint fluid from patients with inflammatory synovitis has higher than normal levels of soluble CD44.[155] The serum CD44 value is elevated in some patients with lymphoma.

Function

CD44 has a diverse range of biologic functions involving cell–cell and cell–matrix interactions in cells other than RBCs.[153] It is an adhesion molecule in lymphocytes, monocytes, and some tumor cells. CD44 binds to hyaluronate and other components of the extracellular matrix and is also involved in immune stimulation as well as signaling between cells.[157]

OK BLOOD GROUP SYSTEM (ISBT SYSTEM 024)

History

Anti-Ok^a was first identified in 1979 in the serum of a Japanese woman (Mrs. Okbutso) who had received a transfusion, and was therefore named after her. After the identification of the gene encoding the Ok protein, the Ok^a antigen attained system status in 1999.[57]

Gene, Protein, and Antigens

The Ok^a blood group antigen is carried on CD147 and is encoded by the *OK* gene at 19pter-p13.2. CD147 (also known as *extracellular matrix metalloproteinase inducer* [EMMPRIN]), M6, OX-47, CE9, basigin, gp42, neurothelin, HT7, 5A11) is an N-glycosylated glycoprotein that passes through the RBC membrane once with its N terminus to the extracellular surface. It is also a member of the IgSF. On SDS-PAGE, CD147 is shown to have an approximate M_r of 35,000 to 69,000. The Ok^a polymorphism is due to an amino acid substitution at residue 92 [Glu for Ok(a+) and Lys for Ok(a−)].[158,159] Ok^a is resistant to treatment of RBCs by proteases, sialidase, DTT, and acid.[7] The eight known Ok(a−) probands are Japanese.

Antibodies

The original example of anti-Ok^a is IgG and is reactive on the IAT; it does not bind complement. This antibody caused reduced cell survival but not HDN. Only one other example of human anti-Ok^a is known.

Expression

The Ok^a antigen on RBCs is well-developed at birth. CD147 has a broad expression pattern in both hematopoietic and nonhematopoietic tissues and is upregulated on activated lymphocytes and monocytes.[160,161]

Evolution

The Ok^a antigen is on RBCs from gorillas and chimpanzees but not on RBCs from rhesus monkeys, baboons, and marmosets.[158] Homologues of the Ok^a glycoprotein have been found in the rat (OX-47 or CE9), mouse (basigin), rabbit, and chicken (neurothelin or HT7).[160]

Function

Human CD147 on tumor cells is thought to bind an unknown ligand on fibroblasts, which stimulates their production of collagenase and other extracellular matrix metalloproteinases, thus enhancing tumor cell invasion and metastasis.[162] In studies with CD147 knockout mice, RBCs were apparently not compromised. CD147 may be involved in the function of the blood-brain barrier[163] and lymphocyte inactivation.[164]

RAPH BLOOD GROUP SYSTEM (ISBT SYSTEM 025)

History

A new polymorphism on RBCs was originally defined by monoclonal antibodies (1D12, 2F7) and called MER2 (M for monoclonal; ER for Eleanor Roosevelt, the name of the laboratory producing the antibodies). Later, the polymorphism was also recognized by human polyclonal antibodies, and when the MER2 antigen attained system status in 1999, the system was named RAPH after the first patient to make the specificity.

Gene, Protein, and Antigens

The MER2 antigen is encoded by a gene located on chromosome 11p15, but it has not been cloned, and the molecular basis of the antigen is not known. Ninety-two percent of English blood donors are MER2-positive, and 8% are MER2-negative. The antigen strength varies among different RBC samples. The antigen is resistant to treatment of RBCs by papain, ficin, and sialidase but sensitive to treatment by trypsin, α-chymotrypsin, and DTT.[7]

Antibodies

The three examples of human anti-MER2 (anti-RAPH) are IgG and reactive on the IAT, and two of the three antibodies bind complement. These antibodies have not caused HDN nor transfusion reactions; indeed, two siblings with the antibody have received numerous crossmatch-incompatible RBC transfusions without problems. The three antibody producers were Indian Jews.[165]

Expression

The antigen is expressed on RBCs of newborns. MER2 is expressed on fibroblasts, and its expression may be reduced on Lu(a−b−) RBCs of persons with the *In(Lu)* gene.

Function

All three people (two probands) with anti-MER2 (anti-RAPH) had renal failure requiring dialysis. It is possible that the protein carrying the MER2 antigen is required for normal kidney function.[165]

OTHER ANTIGENS

Table 5–4 lists antigens that are not included in blood group systems. Three of the blood group collections are carbohydrate antigens (Ii, GLOB, Unnamed). Antigens of the Ii and GLOB collections are discussed in Chapter 6. The other two (Cost, Er) are presumed to be protein antigens, and the antibodies to antigens in these systems are generally not clinically significant. Antigens in the 700 series of low-incidence antigens occur in less than 1% of most populations and have no known alleles. Antibodies to many of these low-incidence antigens have caused HDN.[7] Antigens in the 901 series of high-incidence antigens occur in more than 90% of people, have no known alleles, and cannot be placed in a blood group system or collection. Antibodies to Vel, Lan, At^a, Jr^a, AnWj, PEL, ABTI, and MAM can cause HDN and transfusion reactions.[7,57] Finding blood for patients with any of the antibodies to these antigens can be difficult, and the patient should be encouraged to predeposit autologous units for long-term frozen storage. JMH and EMM are carried on GPI-linked proteins, and antibodies to these antigens are of little clinical concern.

Chapter 9

Human Platelet Antigens

Thomas J. Kunicki • Diane J. Nugent

INTRODUCTION

Platelet Membrane Glycoproteins

Among the variety of glycoproteins on the human platelet surface, there are several that contribute to the immunogenic makeup of the platelet (Table 9–1).

Integrins

The integrins are membrane glycoprotein heterodimers, each consisting of noncovalently associated α and β subunits.[1] The specificity of an integrin is dictated in large part by the identity of its α subunit, even though ligand binding per se may occur with a significant portion of the β subunit. These ubiquitous receptors mediate a wide range of cell adhesion events that are important to every fundamental area of human biology, including embryonal development, immunocompetence, wound healing, and hemostasis. Two platelet integrins figure prominently in the antigenic profile of platelets, the cohesion receptor $\alpha_{IIb}\beta_3$ and the collagen receptor $\alpha_2\beta_1$.

THE PLATELET COHESION RECEPTOR, INTEGRIN $\alpha_{IIb}\beta_3$

The numerically predominant platelet integrin $\alpha_{IIb}\beta_3$ (initially designated *glycoprotein [GP] IIb/IIIa*) mediates the common cohesive pathway that follows platelet activation in vivo (i.e., platelet aggregation supported by the binding of adhesive proteins, such as fibrinogen and von Willebrand factor ([vWF]). The α subunit of this integrin, α_{IIb}, is synthesized exclusively by megakaryocytes. Consequently, $\alpha_{IIb}\beta_3$ is a unique marker for platelets or cell lines with a megakaryocytic lineage. Glanzmann thrombasthenia is an inherited disorder of platelet function characterized by an inability of platelets to bind fibrinogen and undergo agonist-induced aggregation.[2] The molecular defect in this disease involves either a quantitative or a qualitative abnormality of $\alpha_{IIb}\beta_3$.

THE PLATELET COLLAGEN RECEPTOR, INTEGRIN $\alpha_2\beta_1$

Another integrin that contributes significantly to platelet function is the collagen receptor $\alpha_2\beta_1$ (GPIa/IIa). A high-affinity interaction of platelet $\alpha_2\beta_1$ with collagen anchors the platelet more firmly to the matrix, permitting the formation of an activated, procoagulant platelet monolayer.[3] Platelet adhesion in flowing blood mediated by $\alpha_2\beta_1$ is supported by several collagen types, including types I, III, IV, and VI, and the rate of platelet monolayer formation is directly proportional to platelet $\alpha_2\beta_1$ density.[4] Signal transduction is mediated by both $\alpha_2\beta_1$ and the platelet-specific collagen receptor, glycoprotein VI (GPVI) facilitating and likely accelerating platelet activation, leading to aggregate formation.[5,6]

Unlike α_{IIb}, the α_2 subunit is a single-chain molecule and, like several other integrin α subunits, contains an additional 129–amino acid segment known as the I-domain.[1] Inherited platelet deficiencies of the α_2 subunit have been described, and patients with these deficiencies exhibit chronic mucocutaneous bleeding and prolonged bleeding times.[7,8] The expression of $\alpha_2\beta_1$ on platelets differs markedly between normal subjects, depending on the inheritance of α_2 gene (*ITGA2*) haplotypes.[4]

Regulation of $\alpha_2\beta_1$ expression could certainly modulate the antigenicity of this membrane receptor. It is also possible that similar factors influence expression of other platelet integrins, including $\alpha_{IIb}\beta_3$, but the extent to which that occurs remains to be determined. Two other integrins, the fibronectin receptor $\alpha_5\beta_1$[9] and the laminin receptor $\alpha_6\beta_1$,[10] are expressed by platelets, but neither has yet been shown to contribute significantly to platelet immunogenicity.

The Receptor Complex Glycoprotein Ib-IX-V

The functional GPIb complex is a heptamer composed of one molecule of glycoprotein V associated with two molecules each of three other gene products, glycoproteins Ibα, Ibβ, and IX [(2) Ibα:(2)Ibβ:(2)IX:(1)V].[11] With blood flow conditions ranging from low (≤300 sec^{-1}) to high shear (≥1500 sec^{-1}), the initial *transient* arrest of platelets on collagen requires vWF acting as a bridge between collagen and the GPIb complex.[12] The vWF binding site on the complex is located within the amino-terminal domain of glycoprotein Ibα.[13] The Bernard-Soulier syndrome (BSS) is an inherited disorder of platelet function characterized by defective platelet adhesion to subendothelium and a quantitative or qualitative defect in the GPIb complex caused by mutations in genes encoding either the GPIbα, Ibβ, or IX components.[2,14]

ALLOANTIGENS

The proliferation of serologically defined alloantigens on platelet glycoproteins has led to the development of a consensus nomenclature, in which each of the alloantigens is prefixed as human platelet antigen (HPA-).[15] These designations as well as alternate and/or original names are depicted in Table 9–2. The HPA- nomenclature does not take into consideration linkage disequilibrium between these polymorphisms.

Two clinically significant syndromes are the direct result of sensitization to platelet-specific alloantigens: neonatal alloimmune thrombocytopenia (NAIT) and post-transfusion purpura (PTP).

Table 9–1 Functional Properties of Selected Membrane Glycoprotein (GP) Complexes

GP	Alternate Names	Receptor Function	Protein Ligands
Ib-IX-V	GPIb complex	Adhesion	vWF
VI-FcγR	p62	Adhesion	Collagen
$\alpha_{IIb}\beta_3$	GPIIb/IIIa, CD41/CD61	Adhesion	Fibrinogen
		Cohesion	Fibrinogen
			Fibronectin
			Vitronectin
			vWF
$\alpha_2\beta_1$	GPIa/IIa, VLA-2, CD49b/CD29	Adhesion	Collagen
$\alpha_5\beta_1$	GPIc/IIa, VLA-5, CD49e/CD29	Adhesion	Fibronectin
$\alpha_6\beta_1$	GPIc /IIa, VLA-6, CD49f/CD29	Adhesion	Laminin

FcγR, Fc receptor γ chain; vWF, von Willebrand factor; VLA, very late activation (antigen); CD, cell differentiation (antigen).

Neonatal Alloimmune Thrombocytopenia

Neonatal alloimmune thrombocytopenia occurs in neonates and is caused by transplacental transfer of maternal alloantibodies produced by sensitization to paternal alloantigens on fetal platelets (Table 9–3). A correct diagnosis of NAIT must first eliminate other causes of thrombocytopenia that may occur during pregnancy. When severe, NAIT may result in intracerebral hemorrhage leading to hydrocephalus and fetal death. Fetal hydrocephalus, unexplained fetal thrombocytopenia with or without anemia, or recurrent miscarriages should be considered as indicators of possible NAIT.[16] Multiparous women with a history of at least one incident of NAIT should be monitored carefully for subsequent episodes. Postnatal management involves transfusion of compatible platelets, and washed maternal platelets are often used. Antenatal management is controversial but can include a combination of maternal intravenous immune globulin (IVIG) administration, intrauterine platelet transfusions, and corticosteroid therapy, while monitoring fetal platelet counts closely throughout the pregnancy.[16]

Table 9–3 **Alloimmune Thrombocytopenias**

NAIT

Incidence: 1 per 3000 in a retrospective study, 1 per 2200 births in one prospective study.
Maternal antibodies produced against paternal antigens on fetal platelets.
Similar to erythroblastosis fetalis, except that 50% of cases occur during first pregnancy.
Most frequently implicated antigens are HPA-1a and HPA-5b (United States/Europe).
In the case of responsiveness to HPA-1a, there is a high-risk association with HLA-DRB3*0101or DQB1*02.
In the case of responsiveness to HPA-6b, there is an increased association with HLA-DRB1*1501, DQA1*0102 or-DQB1*0602.

PTP

Nearly all of the reported patients have been females previously sensitized by pregnancy or transfusion (<5% were males).
Thrombocytopenia usually occurs 1 week after transfusion.
Homozygous HPA-1b individuals account for a majority (>60%) of cases.
High-risk association with HLA DRB3*0101or DQB1*02.
Enigmatically, the recipient's antigen-negative platelets are destroyed by autologous antibody.

The laboratory diagnosis is normally made by a comparison of maternal and paternal genotypes and a serologic search for antibodies in maternal plasma or serum that react with paternal platelets.

Only a fraction of those mothers negative for the platelet antigen in question deliver infants affected with NAIT. For example, in the western world, responsiveness to HPA-1a is most commonly the cause of NAIT, with severe thrombocytopenia due to maternal alloantibodies occurring in 1 per 1200 pregnancies, yet the frequency of homozygous HPA-1b mothers among white non-Hispanics is much higher (2%). A key to understanding this discrepancy lies in the finding that responsiveness to HPA-1a shows a human leukocyte antigen (HLA) restriction.[17] Individuals who are homozygous for Pro_{33} (homozygous HPA-1b) and responsive to the predominant HPA-1a antigen are almost exclusively HLA DRB3*0101[17] or DQB1*02.[18] In the case of DRB3*0101, the calculated risk factor is 141, a risk level equivalent to that of the hallmark of HLA restriction in autoimmune disease, ankylosing spondylitis and HLA-B27.[19] In contrast, responsiveness of homozygous HPA-1a individuals to the HPA-1b allele is not linked to HLA.[19,20] T cells are the likely candidates for providing HLA restriction in this case, and Maslanka and coworkers[19] provided elegant evidence that in one case of NAIT, T cells that share CDR3 motifs are stimulated by peptides that contain the same Leu_{33} polymorphism that is recognized by anti-HPA-1a alloantibodies.

In five cases of alloimmunization against the less frequent antigen, HPA-6b, there was a clear association between responsiveness and the major histocompatibility complex (MHC) haplotype DRB1*1501, DQA1*0102, DQB1*0602.[21] This alloimmunization likely involves different HLA class II molecules than those involved in immunization against HPA-1a.

Responsiveness to HPA-1a is not the sole cause of NAIT. In a large study of 348 cases of clinically suspected NAIT,[22] 78% of serologically confirmed cases were due to anti-HPA-1a and 19% to anti-HPA-5b. All other specificities accounted for no more than 5% of cases. In reports from other laboratories, the association of NAIT with other alloantigens, such as HPA-3a, HPA-3b, HPA-1b, and HPA-2b, has been noted, but is rare.[23] Obviously, differences in haplotype frequencies between racial or ethnic populations will have an important impact on the frequency of responsiveness to a particular alloantigen.

Haplotype Frequencies in Different Racial/ Ethnic Groups

A substantial amount of information has been accumulated with respect to the relative frequency of the major alloantigen haplotypes among different racial and ethnic populations (see Figs. 9–1 through 9–4). The data for four of the most clinically prominent alloantigen haplotypes are depicted, namely, HPA-1b, HPA-2b, HPA-3b, and HPA-5b (*ITGA2* haplotype 3). Each of these alloantigens represent one of a diallelic system. Consequently, the frequencies of the immunogenic (less common alleles) are depicted, and those of the more common alleles can be deduced.

HPA-1b has a relatively higher frequency among North Africans (0.26), whites of European background (0.15), and black Americans (0.1), and is much rarer among Asians (0.009), Aboriginals (0.008), and Native North Americans (<0.001) (Fig. 9–1). Not surprisingly, the most frequent antigen target in NAIT in white populations is HPA-1a (estimated at 78%).[22] However, among Asians, anti-HPA-1a has never been shown to be involved in NAIT.[24]

HPA-2b has the highest frequencies among Central Africans (0.3), North Africans (0.19), black Americans (0.17), and Native North Americans (0.12) (Fig. 9–2). A somewhat lower frequency is found among whites (0.09), native South Americans (Amerindians) (0.07), Asians (0.05), and Southeast

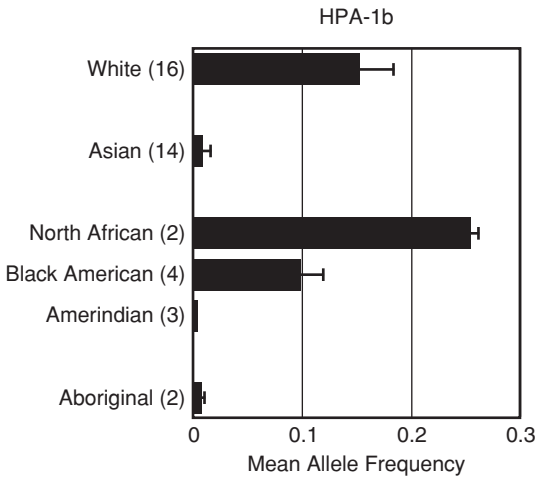

Figure 9–1 HPA-1b frequencies among selected racial/ethnic populations. The frequencies of HPA-1b (abscissa) among the populations listed on the ordinate are depicted. Each data entry (bar) represents the mean and standard deviation for the number of studies indicated in parentheses. References: White,[188–202] Asian,[190,203–215] North African,[216,217] black American,[188–190,203] Amerindian,[188,189,218] and Aboriginal.[202,219]

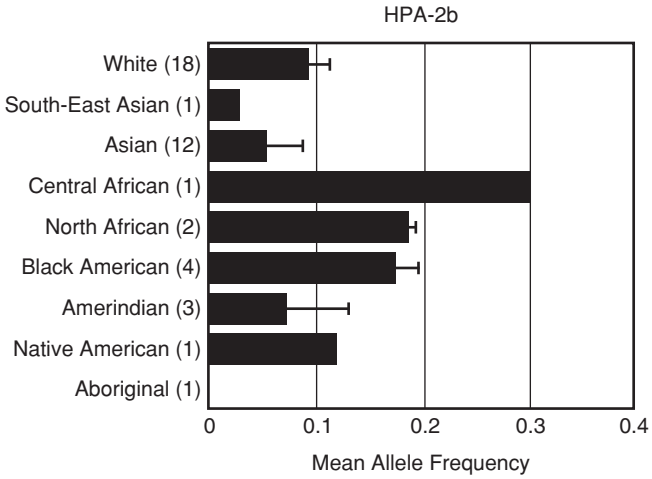

Figure 9–2 HPA-2b frequencies among selected racial/ethnic populations. The frequencies of HPA-2b (abscissa) among the populations listed on the ordinate are depicted. Each data entry (bar) represents the mean and standard deviation for the number of studies indicated in parentheses. References: White,[36,188–203] Southeast Asian,[36] Asian,[36,190,204,205,207–213,215] Central African,[36] North African,[36,216] black American,[188–190,203] Amerindian,[188,189,218] Native American,[220] and Aboriginal.[202]

Asians (0.03), and it is essentially nonexistent among Aboriginals (<0.001). The reports of HPA-2b frequency among Asians have provided disparate values ranging from 0 to 0.1 (mean = 0.05). HPA-2a has been implicated in NAIT among both whites and Asians,[23,25–27] but is much more common among whites.

HPA-3b appears at a very low frequency (0.05) uniquely among Aboriginals. Otherwise, HPA-3b seems to be prominently represented among all other races tested: Asians (0.47), whites (0.4), Amerindians (0.36), black Americans (0.34), and North Africans (0.32) (Fig. 9–3). HPA-3a is a frequent target for alloimmunization in NAIT and PTP among whites.

The highest frequencies of HPA-5b are found among Central Africans (0.25), Aboriginals (0.2), North Africans (0.18), and black Americans (0.17) (Fig. 9–4). Lower frequencies are found among whites (0.09) and Southeast Asians (0.09), and the lowest frequencies occur among Asians (0.03), Amerindians (0.02), and Native North Americans (0.02).

Post-transfusion Purpura

Post-transfusion purpura follows 7 to 10 days after an immunogenic blood (platelet) transfusion (see Table 9–3). It most often affects previously nontransfused, multiparous women. As with NAIT, there is an increased risk to develop PTP among HLA-DR3–positive individuals, and HPA-1a is the antigen most often implicated (in European white populations).[28,29]

Immunochemistry of Platelet Alloantigens

By convention, the designation human platelet antigen has been assigned to alloantigen systems in which the precise polymorphism that accounts for the serologic difference between alleles has been identified. Of 16 HPA systems defined to date (see Table 9-2), 9 are expressed by the integrin β_3 subunit (HPA-1, HPA-4, HPA-6, HPA-7, HPA-8, HPA-10W, HPA-11W, HPA-14W, and HPA-16W), 2 are localized on the integrin α_{IIb} subunit (HPA-3 and HPA-9W), 2 are found on the integrin α_2 subunit (HPA-5 and HPA-13W), 1 is expressed by the GPIbα (HPA-2), 1 by GPIbβ (HPA-12W), and the last is located on the CD109 (HPA-15).

The vast majority of clinical episodes following alloimmunization involve five of these systems: HPA-1, HPA-2, HPA-3, HPA-5, and HPA-15.

HPA-1

The HPA-1 alloantigen system is defined by the Leu_{33}/Pro_{33} polymorphism that is enclosed within a small 13–amino acid loop formed by the pairing of Cys_{26} with Cys_{38}. This region of the molecule is held proximal to the distal cysteine-rich region in the middle of β_3 by a long-range disulfide bond linking Cys_5 and Cys_{435}.[30] The complex structure of the β_3 molecule and the sensitivity of the determinants to this structure is the likely explanation for observed heterogeneity in binding properties of anti-HPA-1a alloantibodies.[31] Although all alloantibodies would bind to the denatured molecule or to recombinant amino-terminal segments of the molecule expressed in *Escherichia coli*,[32] a subset of antibodies appear to require presentation of the antigenic loop within a more native environment (e.g., the nondenatured molecule).[31]Anti-HPA-1a antibodies inhibit clot retraction and platelet aggregation; in the latter case, presumably because they block the binding of fibrinogen.[33]

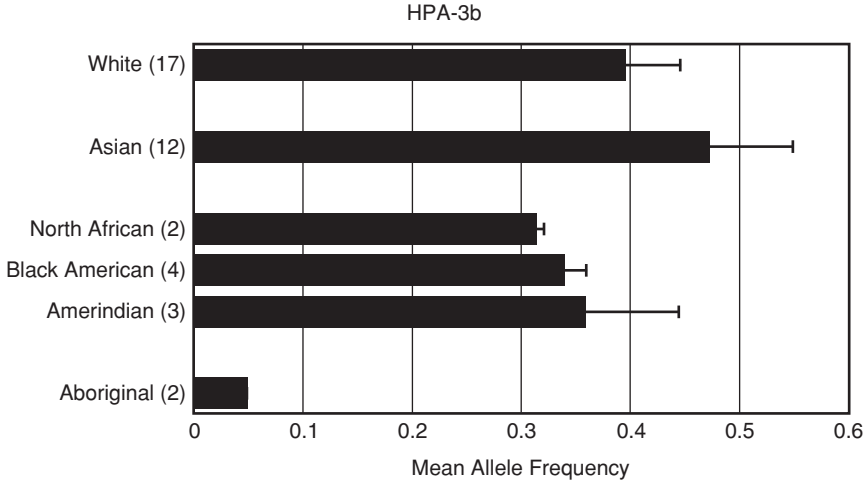

Figure 9–3 HPA-3b frequencies among selected racial/ethnic populations. The frequencies of HPA-3b (abscissa) among the populations listed on the ordinate are depicted. Each data entry (bar) represents the mean and standard deviation for the number of studies indicated in parentheses. References: White,[36,188–202] Asian,[36,189,190,204,207–213,215] North African,[36,216] black American,[188–190,203] Amerindian,[188,189,218] and Aboriginal.[202,219]

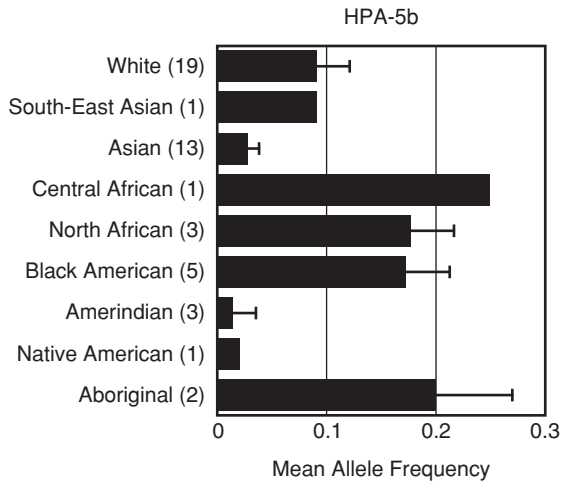

Figure 9–4 HPA-5b frequencies among selected racial/ethnic populations. The frequencies of HPA-5b (abscissa) among the populations listed on the ordinate are depicted. Each data entry (bar) represents the mean and standard deviation for the number of studies indicated in parentheses. References: White,[36,188–203,220] Southeast Asian,[36] Asian,[36,189,190,204,205,207–213,215] Central African,[36] North African,[36,216,217] black American,[188–190,203,220] Amerindian,[188,189,218] Native American,[220] and Aboriginal.[202,219]

Other cells that express β_3, as the β subunit of the vitronectin receptor, including endothelial cells, fibroblasts, and smooth muscle cells, also express HPA-1 epitopes.[34] This could contribute to the complexity of the clinical symptoms in alloimmune-mediated thrombocytopenia. At this time, little, if anything, is known about the involvement of tissues other than platelets in these conditions.

HPA-2

Two previously described polymorphisms of the GP Ib-IX-V complex, termed Ko and Sib, are now known to be reflections of two linked polymorphisms, one of which defines the diallelic system, HPA-2.[35] In the GPIbα sequence, a Thr/Met polymorphism at residue 145 is associated with HPA-2a and HPA-2b epitopes, respectively.

There are several major GPIbα gene *(GP1BA)* haplotypes that can be defined by linkage disequilibrium between the alleles at positions –5 (Kozak), 1018 (Thr145Met; HPA-2), and 1285 (variable number of tandem repeats [VNTR] A, B, C, and D).[36]

HPA-3

The HPA-3 system is associated with an Ile_{843}/Ser_{843} polymorphism of α_{IIb}.[37]

HPA-5

The HPA-5 system is located on the integrin subunit α_2.[38] The detection of this system was facilitated by the development of a highly sensitive murine monoclonal antibody-based monoclonal antibody immobilization of platelet antigen assay.[39] Like the preceding alloantigenic systems, the HPA-5 system is diallelic. Roughly 500 to 2000 copies of α_2 are present on the surface of normal platelets, and each α_2 molecule expresses a single HPA-5 epitope.[38] The integrin α_2 is distributed on a wide variety of cells, but nothing is currently known about the antigenicity of the HPA-5 determinants on receptors expressed by cell types other than platelets.

The density of the $\alpha_2\beta_1$ integrin is known to correlate with the α_2 single-nucleotide polymorphism (SNP) C807T. However, in a study of 79 HPA-5(a/a) mothers giving birth to HPA-5(a/b) offspring, Panzer and colleagues[40] determined that there was no increased risk of maternal-fetal HPA-5 incompatibility among mothers whose genotype is 807T.

There are at least 6 major haplotypes of the integrin α_2 gene *(ITGA2)* that are defined by linkage disequilibrium between alleles at position –52 (C/T), 807 (C/T), and 1643 (A/G; HPA-5).[36]

HPA-15

Kelton and coworkers[41] initially described the Gov system, which is now known to be carried by the 175-kDa glycosyl phosphatidylinositol-anchored glycoprotein CD109 and has been designated HPA-15. Alloantibodies defining each of the two alleles have been detected in patients who had received multiple platelet transfusions[41] as well as in patients who developed NAIT.[42] An A2108C SNP of the CD109 gene results in a Tyr703Ser substitution that defines the HPA-15 alloantigen system.[43] The detection of antibodies against HPA-15 is complicated by variation in expression and instability of CD109 during preparation and storage.[44] Nonetheless, relative to all detected HPA-specific antibodies, HPA-15 was found to account for roughly 6% of alloimmunization in a white population.[44]

ISOANTIGENS

Isoantibodies are produced against an epitope that is expressed by all normal individuals and is not polymorphic. In the area of human platelet immunology, a classic example of isoimmunization occurs when a patient with an inherited deficiency of a membrane glycoprotein has been subjected to multiple platelet transfusions to correct a bleeding diathesis. Glanzmann thrombasthenia and BSS are such inherited disorders, wherein the individual either lacks or expresses an altered form of $\alpha_{IIb}\beta_3$ (Glanzmann thrombasthenia) or GP Ib-IX-V (BSS), respectively. Isoantibodies developed by transfused patients do not distinguish any of the allelic forms of the glycoproteins (such as HPA-3 or HPA-1 alloantigens on $\alpha_{IIb}\beta_3$) but react with the platelets of all normal persons tested. Because the propositus does not express the platelet glycoprotein that carries the epitope in question, these antibodies do not bind to their own platelets.

Isoantibodies in Glanzmann Thrombasthenia

Several cases have been documented in which patients with Glanzmann thrombasthenia have produced antibodies specific for α_{IIb}, β_3, or the $\alpha_{IIb}\beta_3$ complex. Recently, we defined an idiotype (OG) that is associated at high frequency with isoantibodies specific for integrin subunit β_3 generated by Glanzmann thrombasthenia patients.[45,46] Patient OG suffered from persistent often-serious bleeding episodes as a result of both his Glanzmann thrombasthenia phenotype and the fact that he had generated a very high-titered, IgG isoantibody inhibitor of platelet cohesion.[46]

Isoantibodies in Bernard-Soulier Syndrome

Because BSS is less frequently encountered than Glanzmann thrombasthenia, it follows that isoantibodies produced in conjunction with this syndrome are also less frequently encountered. In the only clearcut case of such an isoantibody,[47] the isolated IgG impaired both normal platelet adhesion to subendothelial elements and in vitro aggregation in response to ristocetin and bovine factor VIII.

CD36

The frequency of platelet CD36 (GPIV) deficiency, which occurs most often in Asians and blacks, is approximately 4%, and a subset of these individuals is at risk for immunization against CD36.[48] In five cases of neonatal thrombocytopenia, isoantibodies reactive with CD36 were identified in the mothers of the affected infants. Two black mothers were homozygous for a T1264G substitution in the CD36 gene, and a European white mother was homozygous for a novel deletion of exons 1 through 3. These findings and the results of prior reports indicate that isoimmunization against CD36 can cause neonatal *isoimmune* thrombocytopenia, refractoriness to platelet transfusions, and PTP.[48]

AUTOANTIGENS AND IDIOPATHIC THROMBOCYTOPENIC PURPURA

Autoimmune (or idiopathic) thrombocytopenic purpura (ITP) is the most frequently encountered form of immune thrombocytopenia.[49] This disorder can be classified as acute or chronic on the basis of the duration of the thrombocytopenia, the chronic form persisting longer than 6 months. The acute, self-limiting form occurs predominantly in children, often following a viral illness or immunization, and affects males and females with equal frequency. Although 10% to 15% of childhood ITP lasts longer than 6 months, the chronic form of immune thrombocytopenia is mainly an adult illness and affects twice as many females as males. Life-threatening bleeding occurs in up to 1% of patients with ITP. The reason that some patients sustain severe hemorrhagic complications and others do not remains unexplained, but because of differences seen in the clinical expression of chronic and acute ITP, it has been theorized that the mechanisms of disease for each form stem from different etiologies.[50] Although most autoantibodies apparently induce thrombocytopenia, a minority can induce platelet dysfunction with or without an increase in platelet clearance.[51,52] The proportion of the two types of autoantibody, that which leads to platelet clearance and that which blocks platelet function, may be a very important factor controlling the unpredictable clinical severity of ITP.

It had been hoped that the antigenic targets in acute and chronic forms of ITP might be distinct, so that antigen identity might one day be used as an early indicator of clinical outcome. Subsequent studies have shed more light on this issue and have demonstrated that autoantibody specificity in chronic versus acute ITP is quite similar, particularly in children.[53,54] Nonetheless, a distinction between antigen specificity and an acute versus chronic course in ITP may yet be found in the early stages of the autoimmune response, particularly if additional risk factors such as cytokine response and predisposing high-risk polymorphisms in immune response genes are included in the evaluation.[55–57]

Suppression of Megakaryocyte Production and Maturation

One area where both autoantigen and age may play a role in predicting chronicity in ITP is megakaryocyte expansion and thrombopoiesis.[58–64] Initial studies by McMillan and coworkers[58] showed that immunoglobulin G (IgG) produced in vitro by splenic cells from ITP patients would bind to megakaryocytes but IgG produced by normal splenic cells or purified normal sera IgG would not, thus suggesting that autoantibody might directly interfere with platelet production. Later studies examining the effect of ITP plasma on megakaryocytic growth in culture confirmed that those plasmas containing antiplatelet antibodies resulted in a direct suppression of replication. Of note, these studies once again suggested that there might be significant differences in the etiology of megakaryocytic suppression by plasma from children versus adults with ITP. In addition, autoantigen specificity, especially those antibodies directed against GPIb/IX complex in pediatric patients, may have a profound effect on thrombopoiesis.

In childhood ITP, the mean yield of megakaryocytic cells in culture was significantly reduced in the presence of patient plasmas containing either antiplatelet GPIb autoantibodies alone ($p<0.001$) or antibodies against both GPIb and $\alpha_{IIb}\beta_3$ ($p<0.001$), as compared to control plasmas.[61] There was no significant difference between the mean megakaryocytic yield in cultures containing control plasmas or patient plasmas with either no autoantibodies or autoantibodies specific solely for $\alpha_{IIb}\beta_3$. The ploidy distribution of megakaryocytic precursors in cultures containing either control or ITP plasma was not significantly different. The importance of autoantibodies in the suppression of megakaryocyte production was demonstrated by platelet adsorption studies. Platelet absorption of anti-GPIb autoantibodies in ITP plasmas resulted in a doubling of megakaryocyte production compared to that in the presence of the same plasmas without absorption. On the other hand, platelet absorption of normal control plasma had no effect on megakaryocyte yield.

Studies with plasmas from adult ITP patients demonstrated similar suppression of megakaryocytic production, with one striking difference: The ploidy distribution of megakaryocytic precursors in cultures containing either control or ITP plasma was also significantly different. ITP plasmas that suppressed in vitro megakaryocyte production clearly reduced the percentages of 4N, 8N, and 16N megakaryocytes as well.[63] Houwerzijl and colleagues[64] showed that megakaryocytes in bone marrow aspirates of adult ITP patients exhibit morphologic alterations characteristic of para-apoptosis: mitochondrial swelling with cytoplasmic vacuolization, distention of the demarcation membranes, and chromatin condensation within the nucleus. Importantly, they found that similar para-apoptotic changes could be induced in normal CD34+ cells differentiated to megakaryocytes in the presence of ITP plasma. These authors suggested that the binding of antiplatelet autoantibodies to megakaryocytes may play an important role in initiating the cascade of programmed cell death.[64] These ploidy and para-apoptotic changes were not observed in cultures co-incubated with pediatric ITP plasmas despite their ability to suppress megakaryopoiesis.[61] In addition, when megakaryocytes cultured with ITP plasma were also treated with FMK, a general caspase inhibitor, the differential effect of adult and pediatric ITP plasmas remained. This result would rule out a difference in caspase-mediated apoptotic mechanisms between adults and children as the cause of these findings.[61–64]

It is more likely that a difference in autoantigen epitopes or the intensity of autoantibody binding to certain platelet receptors accounts for the difference in apoptotic changes seen in adult megakaryocytes that is absent in pediatric studies. In addition, since the immune system is still maturing in patients younger than age 5, one would expect to observe increased variability in antibody specificity, affinity, and isotypes among children, with an increased suppression of megakaryocytopoiesis compared to adults.[61,62] Adolescent ITP patients are much more likely to have autoantibodies

specific for the GPIb/IX complex and a clinical course similar to that of adult ITP.[57] Autoantibody binding to the GPIb/IX complex at a certain stage of megakaryocyte development may trigger signaling pathways that predispose to apoptotic changes, resulting in a more profound and lasting suppression of megakaryopoiesis and concomitant thrombocytopenia.

Glycoproteins as Platelet Autoantigens

An extensive characterization of platelet target autoantigens has been accomplished within the past decade. It is now evident that both T and B cells mediate self-reactivity in immune thrombocytopenia. Under normal circumstances, immune recognition may serve to clear damaged or senescent cells, but in ITP patients, these processes result in the pathologic destruction of platelets. In normal individuals, the network of autoreactive T and B cells remains tightly regulated, allowing the effective maintenance of platelet production and integrity. In autoimmune states, following infection or environmental triggers, pathologic platelet autoreactivity results from an imbalance in T-cell signaling and regulation. This state allows the clonal expansion and somatic mutation of B cells through epitope spreading, resulting in pathologic autoantibodies. An understanding of the role of autoantigens in promoting and perpetuating this response has been assisted by an extensive characterization of platelet glycoproteins and glycolipids.[65,66]

Integrin $\alpha_{IIb}\beta_3$

Integrin $\alpha_{IIb}\beta_3$ was the first platelet membrane component to be identified as a dominant antigen in chronic ITP,[67] and subsequent studies from several laboratories have confirmed the important contribution of this receptor to the autoantigenic makeup of the human platelet.[49] An excellent review of the specific assays used to identify serum antiplatelet antibodies and their autoantigen targets has recently been published for readers interested in a detailed description of the technology and use of these assays in the diagnosis of ITP.[68]

Integrin Subunit β_3

Initially, attempts to further localize autoepitopes on either integrin subunit were more successful with regard to β_3. Early on, Kekomaki and coworkers[69] defined a prominent autoantigenic region as the 33-kDa chymotryptic fragment of β_3 located within the cysteine-rich region of β_3, which was bound by both plasma autoantibodies and autoantibody eluted from patients' platelets. Using recombinant fusion proteins containing the extracellular disulfide-rich region of β_3, Beardsley and coworkers[70] more recently confirmed that a disulfide-rich segment of β_3 (residues 468–691) immediately external to the proposed membrane spanning domain (residues 693–721) contains peptide target antigens for autoantibodies from ITP patients.

Fujisawa and colleagues[71] also determined that plasma autoantibodies in 5 of 13 patients with chronic ITP bound to peptides representing β_3 residues 721–744 or 742–762, namely, the carboxy-terminal region of β_3, which is presumed to be located in the cytoplasm of the platelet. Their role in the pathogenesis of immune thrombocytopenia is unclear because this portion of the β_3 molecule is located within the cytoplasm, rather than on the surface, of the resting platelet. However, internal autoantigens are the hallmark of many immune-mediated diseases, such as polymyositis and systemic lupus erythematosus (SLE).[72] As in those diseases, one can postulate that certain autoantigens are normally internal but, at some point, are expressed on the surface of the platelet, perhaps as a result of activation or senescence, at which time the autoantibodies can bind and trigger the removal of platelets from the circulation.

The report by Fujisawa and colleagues[71] is one of many suggesting that autoantibodies to $\alpha_{IIb}\beta_3$ may bind to cryptic epitopes or neoantigens that are expressed on platelet activation or senescence.[73] Platelets normally accumulate IgG on the membrane surface as they age over 7 to 10 days in the circulation and/or become activated, and then they are cleared by reticuloendothelial cells in the spleen.[74] Using a Fab′2 fraction of IgG, it has been shown that normal individuals have autoantibodies in their sera that specifically bind to senescent antigens on red cells and platelets and can mediate clearance of spent or dysfunctional cells.[75,76] The role of these naturally occurring autoantibodies in pathologic immune destruction of cells is unclear. Animal studies suggest that the initial binding of the pathogenic antiplatelet autoantibody may trigger the expression of senescent or cryptic antigens on the platelet membrane, resulting in a second wave of immunoglobulin binding and clearance by naturally occurring autoantibodies.[77]

More recently, additional autoantigenic epitopes have been identified on the β_3 subunit. Nardi and coworkers[78] identified the peptide $\beta_3^{49–66}$ as a site that is bound by a majority of affinity-purified antibodies isolated from serum immune complexes of human immunodeficiency virus-1–infected patients with immune thrombocytopenia. This is not a peptide region that is bound by serum IgG antibodies from control subjects or patients with the classic form of ITP.

Identification of autoimmune epitopes has been aided by the development of the phage-display peptide library. Bowditch and coworkers[79] used a filamentous phage library that displayed random linear hexapeptides to identify peptide sequences recognized by platelet-specific autoantibodies. Plasma antibody eluates from ITP patients were used to select for phage-displaying autoantibody-reactive peptides. They identified anti-$\alpha_{IIb}\beta_3$ antibody-specific phage encoding the hexapeptide sequences Arg-Glu-Lys-Ala-Lys-Trp (REKAKW), Pro-Val-Val-Trp-Lys-Asn (PVVWKN), and Arg-Glu-Leu-Leu-Lys-Met (RELLKM). Each phage showed saturable dose-dependent binding to immobilized autoantibody, and binding could be blocked with purified $\alpha_{IIb}\beta_3$. The binding of plasma autoantibody to the phage encoding REKAKW could be blocked with a synthetic peptide derived from the β_3 cytoplasmic tail; however, binding to the PVVWKN-bearing phage was not inhibited. Using sequential overlapping peptides from the β_3 cytoplasmic region, an epitope was localized to the sequence Arg-Ala-Arg-Ala-Lys-Trp (β_3 734–739).

Using a similar phage peptide display approach, Gevorkian and coworkers[80] identified other mimotopes of platelet autoantigens recognized by autoantibodies in sera from 20 ITP patients. These mimotopes exhibited potential homology with sequences on both β_3 and GPIb, although a specific sequence identity was not proposed.

Integrin Subunit α_{IIb}

In a growing body of literature, it now appears that the α_{IIb} molecule may be the dominant target in the adult form of chronic ITP.[81] Autoantibodies reactive with α_{IIb} were identified in two patients with chronic ITP,[82,83] and in one of these patients, the antibody was subsequently shown to react with a chymotryptic, 65-kDa, COOH-terminal fragment of the α_{IIb} heavy chain.[83] Ethylenediaminetet-raacetic acid (EDTA)-dependent autoantibodies represent a special category that are adsorbed

by autologous platelets when whole blood is drawn in EDTA. In one such case of EDTA-dependent "pseudothrombocytopenia," an IgM antibody was shown to bind to α_{IIb} by immunoblot assay and crossed immunoelectrophoresis.[84]

In subsequent studies, Gevorkian and colleagues[80,85] used phage display to map an autoepitope on α_{IIb}. A filamentous phage library was employed that displays random peptides, 11 amino acids in length, flanked on each side by a cysteine to identify peptide sequences recognized by antiplatelet autoantibodies previously determined to block fibrinogen binding to $\alpha_{IIb}\beta_3$. Phage expressing the sequence CTGRVPLGFEDLC exhibited saturable dose-dependent binding to the immobilized autoantibody that could be blocked with purified $\alpha_{IIb}\beta_3$ or α_{IIb}, but not β_3. This amino acid sequence exhibits partial identity with amino acid residues 4–10 and 31–35 on α_{IIb}. These results suggest that the autoantibodies in question bind to a combinatorial epitope within the amino-terminal 35 amino acids of α_{IIb}.

Other critical autoantigen epitopes have been identified on α_{IIb} in recent years. Using a combination of lysates from platelets with known protein mutations, Kosugi and colleagues[86] demonstrated that one third of patients with chronic ITP produced anti-$\alpha_{IIb}\beta_3$ autoantibodies with a unique specificity. The binding of these autoantibodies is inhibited by the single amino acid substitution (D163A) and a 2-amino acid insertion in the W3 4–1 loop of α_{IIb}.

Autoantigenic epitopes may be conformational, thereby dependent on the tertiary configuration of the molecule. Given the fluid nature of the platelet membrane and the remarkable morphologic changes that can occur on adhesion and activation, it is not surprising that conformational epitopes might be dynamically expressed. In one of the first descriptions of this kind, Shadle and Barondes[87] described a neoantigen on α_{IIb}, which is only revealed following the normal binding of fibrinogen to its receptor, the $\alpha_{IIb}\beta_3$ complex. In addition, serum autoantibodies have been described that demonstrate increased binding to platelets in the presence of calcium chelators, such as EDTA, heparin, or other drugs.[84] Some of this autoantibody specificity may be directed to neoantigens and thus is enhanced following changes in membrane glycoproteins induced by agents such as EDTA or heparin.

Human Monoclonal Autoantibodies

One important question that needs to be resolved is the extent of the autoepitope repertoire on a given platelet glycoprotein antigen. The answer will have an impact on the feasibility of developing therapeutic and diagnostic measures based on epitope specificity. Because the autoantibodies that react with a given epitope are likely to share idiotypes, one can approach this question from two directions, analyzing the epitope repertoire or the idiotype repertoire.

Two studies have addressed the extent of the autoantigen repertoire on $\alpha_{IIb}\beta_3$ by analyzing the competitive binding between human autoantibodies and murine monoclonal antibodies.[88,89] However, the limited number of studies that have used this approach have generated conflicting results, and insufficient data are available to judge the size of the autoepitope repertoire on $\alpha_{IIb}\beta_3$. Additional analyses aimed at epitope localization will be necessary, and perhaps novel approaches will expedite this task. One such novel approach is the development of human monoclonal autoantibodies specific for $\alpha_{IIb}\beta_3$ and other platelet glycoproteins.

Human monoclonal antibodies are an alternative tool in the search for glycoprotein epitopes that are autoimmunogenic in humans. The first human monoclonal antibody against a platelet glycoprotein was derived from an ITP individual producing an antibody against β_3.[72] This human monoclonal antibody detects a neoantigen associated with β_3 that is expressed only on stored or thrombin-activated platelets. A number of human monoclonal autoantibodies specific for the heavy chain of GPIb were generated from the lymphocytes of an ITP patient with serum autoantibody specific for GPIb.[90] The heavy-chain variable region genes of four of these antibodies have been sequenced and found to be markedly homologous to human immunoglobulin, germline, heavy-chain variable region genes.[90] Another human monoclonal autoantibody was produced that is specific for the heavy chain of α_{IIb}.[73] The epitope recognized by this antibody (2E7) has been identified as a contiguous amino acid sequence with residues 231–238 with an immunodominant tryptophan residue at position 235.[91] This was the first time that the precise epitope on α_{IIb} or β_3 recognized by a human antibody had been identified.

The $\alpha_{IIb}\beta_3$ molecule is a member of the greater family of adhesion molecules or integrins, and α_{IIb} has significant homology with other integrin α chains. A comparison of the 220–238 sequences of α_{IIb} and seven other integrin α subunits revealed significant homology between α_{IIb} and other α integrin chains, yet 2E7 did not bind to the other cell types that express these related integrin family members, such as endothelial cells, lymphocytes, monocytes, or neutrophils. In the highly homologous region spanning residues 234–238, α_{IIb} differs from the other α chains only in position 235 (W→L). Ironically, this tryptophan plays a critical role in determining the immunogenic epitope recognized by 2E7.

From the foregoing analysis, it is clear that further studies are required to determine the extent to which the production of human autoantibodies to platelet glycoproteins is clonally restricted. Given a selected number of idiotypes related to autoimmunity to $\alpha_{IIb}\beta_3$, one could potentially use the anti-idiotype (anti-Id) to modulate immunization to $\alpha_{IIb}\beta_3$. Along these lines, it has been reported that IVIG, which is routinely used to reverse acute thrombocytopenia in ITP, may contain anti-Id directed to idiotypes of autoantibody but not alloantibodies that recognize $\alpha_{IIb}\beta_3$.[92] Other investigators have defined a DM idiotype that is characteristic of human autoantibodies that are specific for the GPIb heavy chain.[93] The latter study clearly suggests that the repertoire of idiotypes expressed by human autoantibodies specific for membrane glycoproteins, such as those of the human platelet, will be narrowly defined and, thus, amenable to study.

The production of human monoclonal autoantibodies or recombinant Fab fragments from patients with immune thrombocytopenia provides researchers with specific antibody probes to map target antigens. Human monoclonal antibodies have an advantage over serum antibodies in that they are monoclonal and circumvent problems associated with using a polyclonal serum where many different, low titer autoantibodies may be found with reactivity against a variety of epitopes.

GPIb/IX Complex

Unlike the $\alpha_{IIb}\beta_3$ complex, autoantibodies directed against GPIb are almost universally associated with pathologic immune destruction of platelets. Thus far, no one has described naturally occurring antibodies reacting with GPIb in either resting or activated platelets. Although only 15% to 30% of ITP patients have autoantibodies that bind to GPIb, there is

no background binding of antibodies in normal plasma so the characterization of this antigen is much more straightforward. Autoantibodies to components of the GPIb complex are also frequently encountered in adult chronic ITP.

He and colleagues[94] have made progress in the localization of selected autoantigenic epitopes on the GPIb molecule. Epitopes were most frequently found on a recombinant fragment of Ibα corresponding to residues 240–485, and next most often on a fragment representing residues 1–247. In the case of those antibodies reactive with the former sequence, further epitope mapping identified the dominant determinant as the 9-amino acid sequence TKEQTTFPP (residues 333–341).[94] In some cases in which autoantibody to GPIb/IX was detected, the clinical presentation proved to be particularly severe and refractory to therapy.[93] One case of "pseudo-Bernard-Soulier syndrome" (dysfunction of the Ib-IX-V receptor complex) was reported to be caused by an autoantibody to GPIb.[95] Finally, in a subset of childhood ITP, that associated with *Varicella zoster* infection, the GPV component of this receptor was found to be the dominant target of serum autoantibodies that do not crossreact with viral antigens.[96] At the same time, in another group of children with this disease, it was found that serum antibodies specific for viral antigens can crossreact with normal platelet antigens and may thus contribute to platelet clearance.[97]

The GPIbα heavy chain is a large molecule and contains leucine-rich repeats and a region in the middle of the glycoprotein that is heavily glycosylated. The NH2-terminal region of GPIb is responsible for binding to von Willebrand antigen, mediating platelet adhesion. Theoretically, there could be a variety of antigenic sites on this molecule. However, using anti-Id reagents, it appears that the repertoire of idiotypes expressed by anti-GPIb antibodies from patients with ITP is very narrowly defined.[93]

GPV

In the mid-1980s, when screening for antigen-specific autoantibodies became available, many researchers hoped that the patterns of target antigen reactivity might be predictive of the clinical course of ITP (i.e., acute versus chronic). In fact, an initial report looking at eight children with acute ITP using immunoblot technique failed to demonstrate anti-β_3 antibody even though this was the dominant antigenic target recognized by autoantibodies from patients with chronic ITP.[98] This was followed by a report from the same laboratory[99] demonstrating serum antibody reactivity to Glycoprotein V (GPV) in four pediatric patients with thrombocytopenia associated with varicella (chickenpox) infection. GPV is a thrombin-sensitive, 85-kDa glycoprotein of unknown function on the platelet surface. There was no evidence of immune complexes in these patients or varicella antigens adsorbed to the surface of their platelets. As all of the children with varicella-related ITP and acute childhood form of ITP resolved their thrombocytopenia within 6 months, there was some hope that GPV reactivity would be a marker for mild disease and these patients could escape aggressive immunosuppressive therapy.

Integrin $\alpha_2\beta_1$

Platelet integrin $\alpha_2\beta_1$ is an important collagen receptor on the platelet membrane. Although present in a much lower concentration than $\alpha_{IIb}\beta_3$ or the GPIb complex, this receptor has also been shown to be a target autoantigen in 10% to 20% of chronic ITP patients.[100] Moreover, serum IgG autoantibodies specific for integrin subunit α_2 were identified in a unique case of autoimmune platelet dysfunction following myasthenia gravis.[100] This autoantibody inhibited aggregation of normal platelets induced by collagen or wheat germ agglutinin. This was the first case wherein autoantibodies to α_2 were associated with a chronic hemorrhagic disorder.

Efforts to map the specific epitope on this receptor have been unsuccessful even though a number of groups have suggested that the binding of these antibodies, since they impair function, might be near the binding site of collagen. Deckmyn and colleagues describe a plasma autoantibody directed against a protein comigrating with α_2 and recognized by the patient's antibody when affinity-purified $\alpha_2\beta_1$ was used as antigen.[100] The $\alpha_2\beta_1$ complex was immunoprecipitated from a platelet lysate by the patient's plasma, and purified platelet specific IgG from this patient inhibited aggregation of normal platelets induced by collagen or by wheat germ agglutinin. Dromigny and coworkers[101] described a 48-year-old woman in whom they found increased bleeding times, impaired collagen-induced platelet aggregation, and the presence of autoantibodies directed against $\alpha_2\beta_1$ and the GPIb complex.

GPVI

Sugiyama and coworkers[102] and Moroi and coworkers[103] were the first to identify and characterize autoantibodies from an ITP patient specific for GPVI, a 62-kDa membrane glycoprotein present on both human and murine platelets noncovalently associated with a coreceptor FcγR chain.

More recently, Boylan and colleagues[104] described a patient with a mild bleeding disorder and a moderately reduced platelet count whose platelets were nonresponsive to collagen, although no abnormalities were found in the genomic DNA sequence of *GP6* and the level of platelet *GP6* mRNA was normal. The plasma of this patient was found to contain an autoantibody that binds specifically to GPVI. Because shedding of GPVI on mouse platelets in vivo by infusion of specific anti-GPVI antibody had already been described,[105] it was proposed that in this patient the GPVI/FcγR complex is cleared from the platelet by this autoantibody, resulting in a chronic "acquired" deficiency of platelet GPVI.

This case represents a unique effect of platelet-specific autoantibodies and emphasizes that acquired defects in platelet function can also be a pathologic outcome of autoimmunity to platelets.

Glycolipids as Autoantigens

A number of reports have implicated cardiolipin, lactosylceramide, and other glycosphingolipids (GSL) as autoantigenic targets (Table 9–4).[106,107] Van Vliet and colleagues[107] analyzed the binding of serum IgG/IgM antibodies from 30 ITP patients to platelet glycosphingolipids separated by high-performance thin-layer chromatography. Acidic GSL, namely sulfatides and gangliosides, were identified as the major targets of serum autoantibodies. Thirteen of the 30 sera, five with anticardiolipin antibodies, had antibodies that bound to

Table 9–4 Glycolipid Antigens of Platelets

Cardiolipin
Lactosylceramide
Glycosphingolipids (GSL)
Acidic: sulfatides/gangliosides
Monogalactosyl sulfatide (16/6 idiotype)
Neutral: globotriosyl ceramide
Globotetraosyl ceramide

sulfatides; four sera showed antibody binding to gangliosides. Koerner and colleagues[106] employed a more efficient phase partition separation of acidic GSL from neutral GSL and were able to demonstrate that serum antibodies specific for neutral GSL were more characteristic of ITP. Two classes of GSL autoantigens were defined: those associated with general autoimmunity and detected in the sera of patients with either SLE or ITP, and those peculiar to platelet-specific autoimmunity and detected only in the sera of ITP patients. Two GSL forms belong to the platelet-specific group, but they are present at minute levels, and further characterization awaits large-scale purification. One half (6/12) of patients with ITP had serum IgG or IgM antibodies that bound these platelet-specific GSL. Sera from none of 10 patients with nonimmune thrombocytopenia, none of 10 patients with SLE, and only 1 of 18 normal subjects gave positive reactions with the platelet-specific GSL group. The general GSL antigen group includes globotriaosyl ceramide, globotetraosyl ceramide, and a third unidentified neutral GSL. Antigens in the general group were bound by IgG or IgM antibodies in the sera of 10 of 10 patients with SLE, 8 of 12 patients with ITP, and none of 10 patients with nonimmune thrombocytopenia or 18 control subjects. These findings provide compelling support for a role of neutral GSL as antigenic targets in selected cases of ITP.

Animal Models of ITP

Many investigators have searched in animals for clinical correlates of human ITP. These attempts have been largely unsuccessful, but an exception may have recently evolved from concerted studies in dogs. As pointed out in a recent series of reports by Lewis and Meyers,[108] there is now substantial evidence that ITP in dogs and ITP in humans are clinically analogous syndromes. In 32 cases of canine ITP, increased platelet-bound IgG was detected in a majority of the animals (30 of 32), and immunoglobulin eluted from the platelets of 11 of 19 affected dogs bound to homologous normal canine platelets.[108] Furthermore, immunoglobulin specific for integrin subunits α_{IIb} and/or β_3 was detected in sera of 4 of 17 dogs tested. They have concluded that, in canine ITP, immunoglobulin bound to the surface of platelets is directed against host antigens and that the target antigen is frequently $\alpha_{IIb}\beta_3$. Given the similarities between these findings and the cumulative experience with human ITP, the canine model may prove to be a valuable tool to further understand the pathogenesis of the autoimmune response to platelet antigens.

Recent attempts to create a murine model of ITP have produced initial results that are promising for researchers interested in studying the pathophysiology of immune-mediated thrombocytopenias. Monoclonal antibodies of different IgG subclasses directed against mouse $\alpha_{IIb}\beta_3$, β_3, GPIba, GPIb/IX, GPV, and CD31 were generated. When injected into mice, monoclonal antibodies against GPIb/IX, GPV, CD31, and linear epitopes on β_3 had mild and transient effects on platelet counts and induced no spontaneous bleeding. On the other hand, anti-GPIba monoclonal antibodies induced profound irreversible thrombocytopenia (to <3% of normal) by an Fc-independent mechanism.[65]

Immunologic Abnormalities in ITP

Increasing insights into the etiology and pathophysiology of ITP have stimulated an examination of immune abnormalities that distinguishes adult from childhood immune thrombocytopenia. Given the elegant and extensive regulatory network inherent in the immune system that optimizes our response to external organisms and safeguards us against autoimmune disease, one wonders why antibodies to platelet antigens appear to be preserved in our repertoire of immunoglobulins.

Kazatchkine and coworkers[109] were among the first to demonstrate the presence of antiplatelet antibodies in normal human serum and anti-Id antibodies in IVIG, suggesting that immunoglobulin reactive with common platelet antigens, such as the GPIb/IX complex and $\alpha_{IIb}\beta_3$, are critical components of the naturally occurring autoantibody repertoire.[109–115] These observations, along with a growing body of evidence, suggest that antiplatelet antibodies are produced as a result of epitope shift[116,117] after exposure to certain infectious organisms or external antigens. This response must be tightly controlled with a network of regulatory cells and plasma factors, such the anti-Id antibodies found in IVIG.[115,118,119] In childhood ITP, which is seasonal and transient in nature, the regulatory network can usually restore itself to proper order within 6 months following the acute insult in a majority of patients.[57]

In animal models, loss of peripheral tolerance to self-antigens is emerging as a possible mechanism for autoimmune disease, with particular focus on the regulatory CD4+25+ T-lymphocyte subset.[120–122] These cells prevent autoimmune disease by modulating self-reactive T cells and secretion of suppressor cytokines, such as interleukin-10 (IL-10) and transforming growth factor beta (TGF-β).[123,124] As summarized in the following section, the finding of inherent T-cell abnormalities and alterations in the expression of accessory molecules on autoreactive T cells provides a novel avenue for the development of immunotherapy in ITP.[119,125]

T Lymphocytes

As in other autoimmune diseases, elevated numbers of T-cell receptor (TCR) γ/δ-positive T lymphocytes have been noted in both acute and chronic ITP patients, as initially described by Ware and Howard.[126] Analysis of the nucleotide sequences used by these TCR γ/δ T cells demonstrated a diverse set of VDJC gene rearrangements, characteristic of a superantigen response. Further evidence for T-cell reactivity in ITP came from the observations that isolated T-cell clones showed in vitro proliferation against allogeneic platelets, the numbers of Vβ8+ T cells were elevated, and platelet stimulation resulted in measurable IL-2 secretion.[126] These results provided the first evidence that patients with ITP have platelet-reactive T lymphocytes identifiable at the clonal level.

T-cell proliferative responses to platelet membrane glycoproteins were examined in 21 patients with chronic ITP or SLE, with or without thrombocytopenia, and 10 healthy donors.[127] T cells from all subjects failed to respond to detergent-soluble native glycoproteins, but tryptic peptides of integrin $\alpha_{IIb}\beta_3$ stimulated T cells from nearly all subjects, including the normal individuals. Similar T-cell proliferation in healthy individuals in response to $\alpha_{IIb}\beta_3$ had been described previously by Filion and colleagues.[128] These findings implied that some autoreactive T cells, directed against membrane antigens present on platelets, were not necessarily eliminated by intrathymic deletion but are present in a suppressed state in normal individuals. In the ITP patients, the T-cell response was restricted by HLA-DR, the responding T cells had a CD4+ phenotype, and the proliferation was accelerated relative to normal subjects, suggesting in vivo T-cell activation.[128] None of the peripheral blood mononuclear cell culture supernatants from healthy donors contained a significant amount of IgG

anti-$\alpha_{IIb}\beta_3$ antibody, but all showed trypsin-digested $\alpha_{IIb}\beta_3$-induced T-cell proliferation. These findings led to the conclusion that CD4+ HLA-DR-restricted T cells reactive with $\alpha_{IIb}\beta_3$ epitopes are involved in production of antiplatelet autoantibody and are implicated in the pathogenesis of chronic ITP.

T-cell activation, proliferation, and T-B cell cognate recognition in response to specific autoantigens require signaling through a variety of membrane immune receptors. The MHC and TCR were recognized as major receptors for many years, but it is now understood that there are accessory molecules that facilitate or modulate the response and that these are potential therapeutic targets in treating ITP.[119,125,129] Antigen-presenting cells, which include B cells as well as macrophages, require specific recognition and signaling through the receptors B7, LFA-3, and ICAM-1, whereas the T cell employs the receptors CD28, LFA-1, and CD2.[125,130] Increased expression of CD40L on platelets may be a normal response of platelets activated by infection or other inflammatory mediators. However, this increase in CD40L has the potential to drive B-cell production of platelet autoantibody. Two research groups reported that administration of a humanized anti-CD40L antibody resulted in increased T-cell tolerance in patients with ITP, suggesting that blockade of CD40L may prove to be a useful therapeutic approach.[125,131] Likewise, Zimmerman and colleagues[132] reported that IVIG and dexamethasone induced an alteration of T-lymphocyte subsets and suppression of T-lymphocyte proliferation in vitro in ITP patients. Although equally effective in the treatment of ITP in children, they found that high-titer anti-D immunoglobulin caused significantly less inhibition than IVIG or dexamethasone in children with chronic ITP, and anti-D did not affect T-lymphocyte subsets.

Cytokines

Considerable work has been focused on the measurement of cytokines in ITP in an effort to further characterize the influence of T-helper subsets (Th0, Th1, and Th2) in the autoimmune etiology of this disease.[130,133] Unfortunately, the majority of these studies draw conclusions based on a single cytokine profile determination. Because cytokine signaling is dynamic and may fluctuate rapidly, it is difficult to draw valid conclusions from a single assay. In addition, the presence of soluble cytokine receptors may confound the results if these are not measured directly in parallel with cytokines. To distinguish a normal versus pathologic immune response in both acute and chronic ITP, multiple samples must be obtained over time, with attention paid to both the cytokines and their soluble receptors. The referenced studies have incorporated multiple samples and controls in the overall analysis. Nonetheless, a degree of disparity remains between the results obtained in children[57] versus those found in adults,[134,135] which likely reflects a difference in the primary pathophysiology of the thrombocytopenia.

In pediatric ITP patients, a Th1 type of cytokine response is the customary finding, characterized by very low IL-4 and IL-6, but elevated levels of IL-2, interferon-γ, and TNF-β.[136] In adults with chronic ITP, malignancy associated with ITP, or the autoimmune lymphoproliferation syndrome associated with defects in the Fas apoptosis pathway, there are elevated levels of IL-10, IL-11, IL-6, and IL-13.[137–140] One would expect that successful therapy might be associated with favorable changes in cytokine profiles. Although many treatment regimens have been efficacious in ITP, in only a few instances has there been documentation of cytokine profile changes following therapeutic intervention with the most common drugs, IVIG and anti-D immunoglobulin.[57,132,141]

Bussel and coworkers[141] compared the changes in IL-6, IL-10, MCP-1, and TNF-α cytokine levels after treatment with IVIG and anti-D in thrombocytopenic adults. There was an increase in all but TNF-α within 2 hours after administration of anti-D. After IVIG, there was a significant increase in IL-10 levels within 4 hours (but not 2 hours) post-therapy. It was concluded that the early increase in these macrophage-synthesized cytokines following anti-D administration reflects the substantial interaction of antibody-coated erythrocytes with macrophages.[132] Mouzaki and coworkers measured a panel of Th0-, Th1-, and Th2-related cytokines over 0.5 to 5 years following the onset of ITP and found that patients who did not convert from a Th1- to Th2-dominant cytokine profile were more likely to have a chronic or relapsing course of thrombocytopenia.[57] Interestingly, the same group of researchers found that adults with ITP were likely to have a striking polarization toward Th1 phenotype, but this profile did not change in response to disease status over time or with treatment.[135] This is in contrast to another group who found an association between improved platelet count and disease outcome in adults with a lower Th1/Th2 ratio.[134] Again, these differences may arise from disparities in population, differences in timing and technology of assays, and differences in treatment regimens, which vary greatly between centers. A better understanding of the relevance of Th1/Th2 ratio and cytokine profiles will emerge with the establishment of coordinated clinical trials and the incorporation into such trials of the newly recognized components of the cellular immune response, such as CD4+25+ (Treg) cells and the antigen-specific idiotypic network.

DRUG-INDUCED IMMUNE THROMBOCYTOPENIA (QUININE/ QUINIDINE PURPURA)

Although drug-induced immune thrombocytopenia (DITP) may be a complication of therapy employing a variety of drugs, it is most frequently seen in the United States with the administration of quinine and quinidine.[142] It has been proposed that the following criteria be met before an individual can be considered to have DITP: the patient is not thrombocytopenic before administration of the drug; thrombocytopenia follows drug ingestion and begins to reverse shortly after cessation of drug; thrombocytopenia does not recur after cessation of drug treatment; and all other causes of thrombocytopenia are ruled out.[143]

Cumulative evidence now favors a mechanism whereby the drug induces the expression of a neoantigen on the platelet surface[144] that is recognized by circulating antibodies only in the presence of the drug. The observation that platelets from BSS patients (lacking Ib-IX-V) failed to lyse in the presence of drug-dependent antibody, specific drug, and complement, was the first indication that a specific platelet antigen is recognized by such antibodies.[145] This finding led other laboratories to confirm that purified GPIb/IX would compete for drug plus antibody and was therefore likely to contain the antigenic epitope in question. Evidence of direct binding of such antibodies to GPIb/IX was first provided by Chong and coworkers,[146] and Berndt and coworkers[147] established that the complex of both Ib and IX is likely required for maximum antigen expression.

Chong and coworkers[148] showed that one quinine-dependent antibody binds to an epitope on the amino-terminal portion of Ibα, and five other quinine-dependent antibodies recognize a complex-specific epitope proximal to the membrane-associated region of GPIb/IX. Each of six quinidine-dependent antibodies contained two specificities, one for the same Ib/IX complex epitope described above, the other for IX alone. Additional observations were that antibodies reactive with GPIb/IX are more predominant (12/12 patients) than those that bind $\alpha_{IIb}\beta_3$ (3/12 patients), and antibodies specific for Ib-IX-V are present in titers 8- to 32-fold higher than the corresponding antibodies that bind to $\alpha_{IIb}\beta_3$ in the same patient samples. In each case, those antibodies that bound to Ib-IX-V were distinct from those that recognized $\alpha_{IIb}\beta_3$. The specificity of quinine- and quinidine-dependent antibodies for a conformation-sensitive epitope(s) on the GPIX component of the complex was confirmed by Lopez and colleagues[149] using monoclonal antibody inhibition assays. Rifampicin-dependent antibodies bind to a similar or identical epitope on GPIX as that recognized by quinine-dependent antibodies.[150]

Regions of $\alpha_{IIb}\beta_3$ that bind to quinine- or quinidine-dependent antibodies have also been further localized by Visentin and colleagues.[151] Of 13 patient sera containing such antibodies, 10 were reactive with both GPIb-IX and $\alpha_{IIb}\beta_3$, 2 reacted with Ib-IX alone, and 1 reacted with $\alpha_{IIb}\beta_3$ alone. Again, in those sera where both specificities were identified, the anti-Ib-IX-V antibodies were distinct from those that bound to $\alpha_{IIb}\beta_3$. Seven sera containing anti-$\alpha_{IIb}\beta_3$ antibodies were further characterized: Three bound only to the $\alpha_{IIb}\beta_3$ complex, one bound to α_{IIb} alone, and three bound to β_3 alone. On β_3, a 17-amino acid sequence in the "hybrid" and PSI homology domains of β_3 is a dominant epitope.[144] In the case of sulfonamide-induced immune thrombocytopenia,[152] the causative antibodies are almost exclusively specific for calcium-dependent (complex-specific) epitopes on the integrin $\alpha_{IIb}\beta_3$.

In addition, sera from 20 patients with quinine-induced thrombocytopenia and 5 patients with DITP following intake of carbimazole were found to have drug-dependent antibodies specific for PECAM-1.[153] Thus, integrin $\alpha_{IIb}\beta_3$ and the GPIb-IX-V complex are not the only antigenic targets in DITP.

One additional intriguing aspect of certain cases of DITP is worthy of mention, because it may have an important bearing on our understanding of the autoimmune response to platelets in general. Based on anecdotal evidence, it has been suspected that some cases of chronic ITP[154] are initiated in clinical situations that, from all appearances, could be classified as DITP. The only difference is that selected autoantibodies persist long after exposure to the insulting drug. Direct evidence to support this contention was obtained by Nieminen and Kekomäki.[155] In that report, it was found that the DITP patients with GPIb/IX-specific antibodies, despite a very intense and acute thrombocytopenia, recovered promptly after drug removal. On the other hand, DITP patients with more prolonged thrombocytopenia and persistently elevated platelet immunoglobulins, more than 1 month after drug removal, had antibodies that reacted with additional target antigens, including integrin $\alpha_{IIb}\beta_3$. To better understand the pathogenesis of both DITP and classic ITP, in the future it may become important to distinguish the acute but readily reversible clinical situation that we accept as DITP from the more complex disease situation that may be initiated by drug exposure but evolves into a more classic form of ITP.

Compounds that inhibit the binding of fibrinogen to the platelet receptor $\alpha_{IIb}\beta_3$ are a novel group of antithrombotics that are being used more frequently to inhibit acute episodes of thrombosis or restenosis in patients with cardiovascular disease.[156] Thrombocytopenia has been observed within hours of the initiation of treatment with such inhibitors and has become a recognized side effect of this drug therapy. Accumulated evidence argues that drug-dependent antibodies may be responsible for platelet destruction in a substantial portion of the affected recipients. Because these antibodies are often detected in persons not previously exposed to the inhibitor drug, there is a high likelihood that thrombocytopenia is caused by naturally occurring or pre-existing antibodies. This complication of antithrombotic therapy warrants further investigation.

HEPARIN-ASSOCIATED IMMUNE THROMBOCYTOPENIA

Heparin-induced thrombocytopenia (HIT) is a life-threatening condition that occurs in 1% to 5% of patients treated with unfractionated high-molecular-weight heparin. In these patients, use of high-molecular-weight heparin results in thrombocytopenia and can be associated with life-threatening thrombotic complications. Unlike quinine- or quinidine-dependent antibodies, the actual binding of heparin-dependent antibodies to the platelet surface appears to be of very low affinity, and was difficult to demonstrate in earlier studies, until the report of Lynch and Howe.[157] It was also determined that heparin-dependent antibodies differ from other forms of drug-dependent antibodies in that they can often be *activating*, causing not only thrombocytopenia, but also heparin-dependent platelet aggregation, thromboxane synthesis, and granule release that can be quantitated by preloading platelets with [^{14}C]serotonin. The consequences of HIT therefore are multiplied by often serious thrombotic complications. Approximately 30% of these patients die, with an additional 20% developing vascular occlusions that result in gangrene and subsequent amputation.[158]

Although the precise mechanism of heparin-dependent antibodies binding to platelets eluded investigators for many years, it was generally accepted that the activating properties of heparin-dependent antibodies must be mediated by Fc-dependent binding to platelets. In this regard, Kelton and colleagues[159] showed that the platelet release reaction induced by heparin-dependent antibodies could be blocked by pretreating platelets with human or goat IgG Fc fragments, Adelman and colleagues showed that the Fab regions of heparin-dependent antibodies alone are not sufficient to cause platelet activation,[160] Chong and colleagues[161] showed that purified rabbit IgG and its Fc, but not Fab, fragments markedly inhibited platelet aggregation induced by heparin-dependent antibodies, and a number of groups observed that the monoclonal anti-Fc receptor antibody, IV.3, could block platelet activation by HDA.[159,162]

It is now accepted that HIT is caused by antibody specific for a complex of heparin (H) and platelet factor 4 (PF4). H–PF4 complexes, which are detected in 85% of patients with HIT,[163] can bind to the membrane of platelets[164–166] or endothelial cells,[164] leading directly to thrombocytopenia in the former case. In those cases in which the heparin-dependent antibodies are IgG, the Fc portion can crosslink to the platelet FcγRIIA receptor, inducing platelet activation, release, aggregation, and thrombosis.[164,167,168] However, HIT can also

be associated with antibodies of IgM and IgA isotypes,[169] in which case the Fc(μ)R of lymphocytes or the Fc(α)R of monocytes and neutrophils, as well as complement activation, may play a role in the pathology of this disorder.

Poncz[170] has proposed that this disease is probably initiated by an excessive release of platelet PF4, which then binds to the platelet membrane or other vascular cell membranes and initiates HIT by three mechanisms that are not mutually exclusive. First, the infused heparin could neutralize a proportion of membrane surface PF4, thus enhancing local thrombosis. Second, the excess PF4 could be mobilized into H–PF4 complexes that stimulate HIT antibody production. Third, the remaining PF4 that has been complexed with heparin on the vascular surfaces could be bound by HIT antibodies and through an FcγRII-mediated reaction, lead to additional platelet activation, thrombosis, and inflammation. When present at equimolar concentrations, unfractionated heparin and tetrameric PF4 can form ultralarge (>670 kDa) complexes that are particularly more reactive with respect to binding to HIT antibodies and capacity to promote FcγRII-dependent platelet activation.[171] These processes would stimulate further PF4 release, exacerbating the clinical manifestations.

Alternative protein targets may be involved in selected cases of HIT. For example, in 9 of 15 patients with HIT that lacked detectable antibodies to H–PF4 complexes, Amiral and coworkers[172] found evidence of autoantibodies specific for the chemokines neutrophil-activating peptide 2 (NAP2) and IL-8. PF4 is about 60% homologous to NAP2 and 40% homologous to IL-8, leading to the proposal that HIT involving these proteins could proceed along a mechanism similar to that invoked for PF4.

Chapter 10

Human Leukocyte and Granulocyte Antigens and Antibodies: The HLA and HNA Systems

Ena Wang • Sharon Adams • Francesco M. Marincola • David F. Stroncek

INTRODUCTION

The structure, function, and nomenclature of the human leukocyte antigen (HLA) and human neutrophil antigen (HNA) systems and their relevance in transfusion medicine are reviewed in this chapter. Analysis of HLA gene products is applied in several settings, including the selection of compatible donor–recipient pairs for hematopoietic stem cell transplantation, selection of HLA-compatible platelet components for transfusion to thrombocytopenic patients refractory to platelet transfusions, and screening of genetic factors that may contribute to the prevalence of diseases. In addition, we discuss new applications that have broadened the relevance of HLA in immune pathology. HLA phenotypes are being used to determine the eligibility of patients for epitope-specific immunization to treat cancer or viral infections. Tetrameric HLA–epitope complexes (tHLA) are being used to enumerate antigen-specific T-cell responses. Furthermore, the molecular identification of T-cell epitopes associated with distinct diseases and characterization of the communication between immune effector cells through HLA–HLA ligand interactions has extended the relevance of the HLA antigen system to several biologic fields, which encompass natural killer (NK) and cytotoxic T-cell function, and antigen recognition in the context of infection, autoimmunity, graft-versus-neoplasia effect, and autologous cancer rejection.

Neutrophil antigens are a group of immunogenetic molecules expressed by neutrophils but few if any other blood cells. The antigens are located on a number of different and otherwise unrelated molecules. A few of these polymorphisms affect neutrophil function, but the importance of these antigen systems is primarily due to clinical problems caused by antibodies directed to these antigens, including alloimmune neonatal neutropenia, autoimmune neutropenia of childhood, and transfusion-related acute lung injury (TRALI).

HUMAN LEUKOCYTE ANTIGENS

Genes of the Major Histocompatibility Complex

Human leukocyte antigens are a family of genes clustered in the short arm of chromosome 6 and are the human version of the major histocompatibility complex (MHC). MHC was initially identified in mice as the antigen responsible for graft rejection between genetically unrelated strains (transplantation antigens).[1] HLA genes comprise a group of coding sequences that regulate the expression of molecules with similar but not identical function as the mouse MHC.

The HLA genes reside in a region that spans approximately 4000 kilobases (kb) of chromosome 6 band p21.3[2] (Fig. 10–1). This region contains a number of genes and pseudogenes characterized by sequence homology and functional similarity. Of them, 47 are officially recognized by the World Health Organization (WHO) nomenclature committee.[3] The HLA genes are separated into classical and nonclassical categories. Classical HLA genes have been well characterized and are clearly associated with presentation of antigen to immune cells. The classical genes include HLA class I (HLA-A, HLA-B, and HLA-C) and class II (HLA-DR, HLA-DQ, and HLA-DP). The nonclassical HLA genes include HLA-E, HLA-F, HLA-G, HLA-DM, and HLA-DO.

Human leukocyte antigens and HLA-associated genes can be grouped into three subregions according to chromosomal location. On the centromeric end of the MHC region is the HLA class II region, comprising genes encoding the α- and β-chains of HLA-DR, HLA-DQ, HLA-DP, HLA-DM, and HLA-DO as well as transporter associated with antigen processing (TAP) and psmB genes. The class I region is most telomeric and includes HLA-A, HLA-B, and HLA-Cw loci; the nonclassical HLA-E, HLA-F, and HLA-G loci; and several pseudogenes. Located between the class I and class II region is the class III region, which encodes several genes that are not functionally related to the HLA genes, such as complement components, heat shock proteins, and tumor necrosis factor. The functional basis for the genetic link of the genes in the class III region to those in the class I and II region is unknown, although the immunologic function of the genes in the class III region and their inclusion in the MHC seems more than coincidental.

Genetics, Structure, and Function of HLA molecules

Genetics of HLA Molecules

In general, HLA class I and II genes have a very similar structure and function.[4–6] Both class I and class II molecules

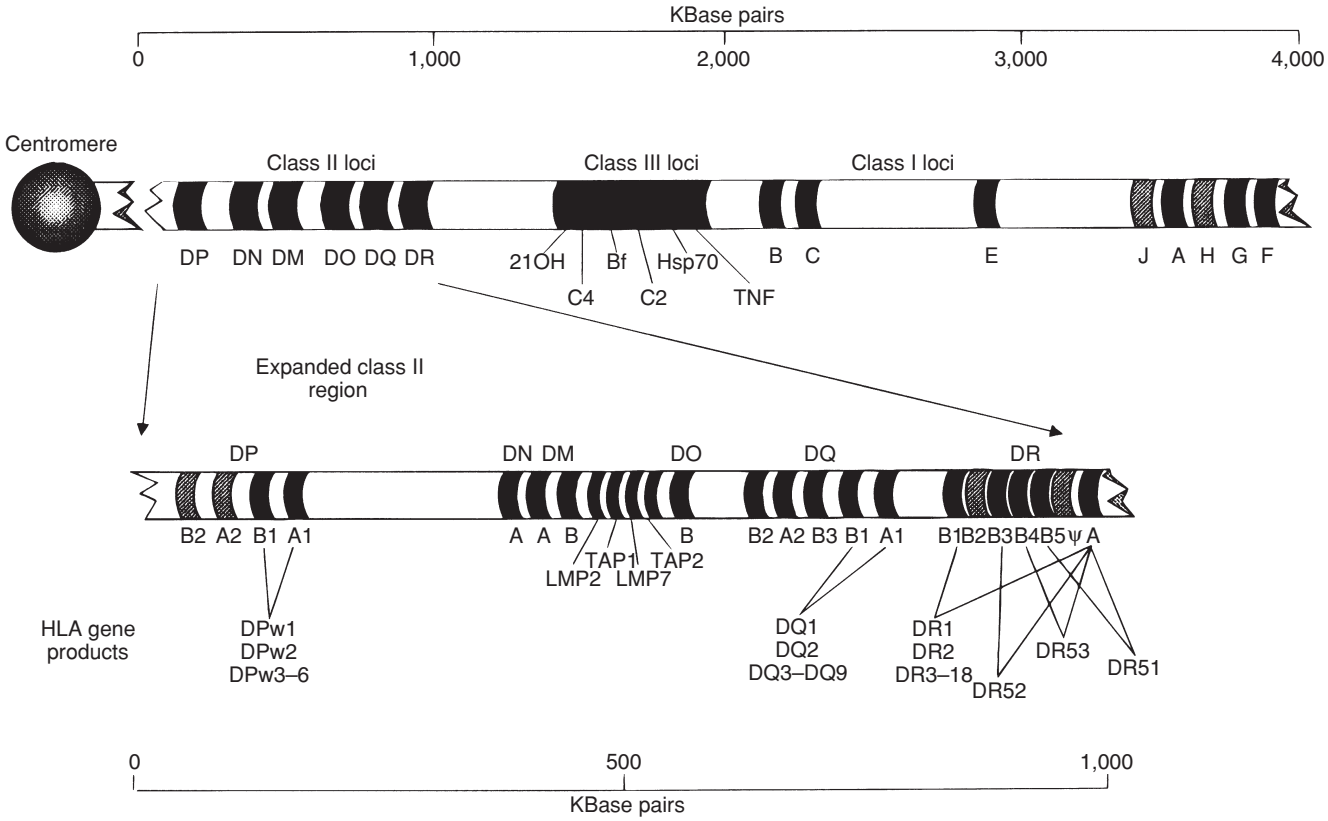

Figure 10–1 Physical map of the HLA genetic complex, illustrating the clusters of genes according to the class of encoded gene products. The symbol ψ represents four DRB pseudogenes, designated 7, 8, and 9. Other pseudogenes are shown in gray. (From Hoffman R, et al. Hematology: Basic Principles and Practice, 4th ed. Philadelphia, Churchill Livingstone, 2005.)

are made up of a heavy and light chain. The genes encoding the HLA class I heavy chain and both the HLA class II heavy and light chains are located in the MHC region. All HLA class I molecules share the same light chain, β_2-microglobulin, which is encoded outside the MHC on chromosome 15.[7]

Three separate genes encode the class I HLA-A, HLA-B, and HLA-C heavy chains, *HLA-A*, *HLA-B*, and *HLA-C*, and the three have a similar structure. Each contains eight exons encoding for the α_1, α_2, and α_3 extracytoplasmic domains, a transmembrane domain, and a cytoplasmic tail (Fig. 10–2). The first exon of the class I α chain encodes a leader sequence. Exons 2 through 4 are highly polymorphic and encode extracellular domains, α_1, α_2, and α_3, that are responsible for peptide binding and T-cell receptor (TCR) engagement. Exon 5 encodes the transmembrane region, exons 6 and 7 the cytoplasmic tail, and exon 8 the 3′ untranslated region.

The HLA class II molecules are heterodimers composed of an α and β chain of approximately the same size. The genes encoding the class II α and β chains have a similar structure, but the α chain has 5 exons and the β chain has 6 exons. For both the α and β chain genes exon 1 encodes the leader peptide, and exons 2 and 3 encode the two extracellular domains. For the β chain gene exon 4 encodes the transmembrane domain, exon 5 the ctyoplasmic tail, and exon 6 the 3′ untranslated region. For the gene encoding the α chain exon 4 encodes the transmembrane domain and the cytoplasmic tail and exon 5 encodes the 3′ untranslated region.

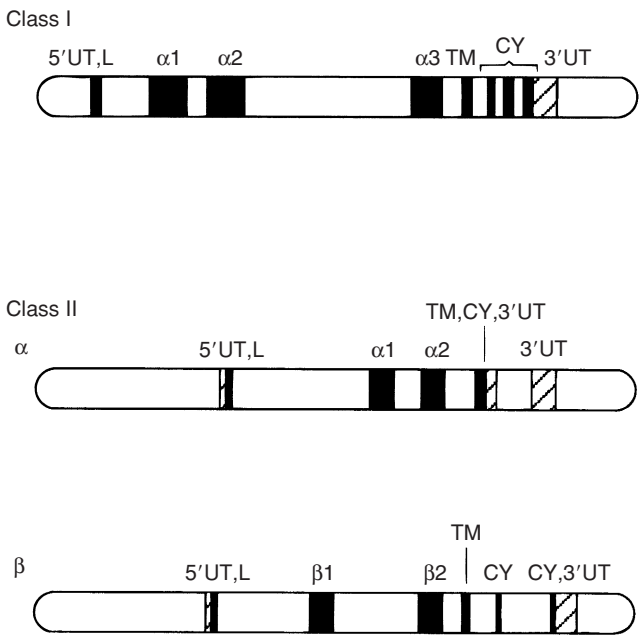

Figure 10–2 The organization of class I and II MHC genes. 5′UT and 3′UT are the untranslated regions in the 5′ and 3′ ends of the gene. L is the leader sequence, TM the exons encoding the transmembrane domains, and CY the exons encoding the cytoplasmic tails. (From Germain RN, Malissen B. Analysis of the expression and function of class-II major histocompatibility complex-encoded molecules by DNA-mediated gene transfer. Annu Rev Immunol 1986;4:281–315.)

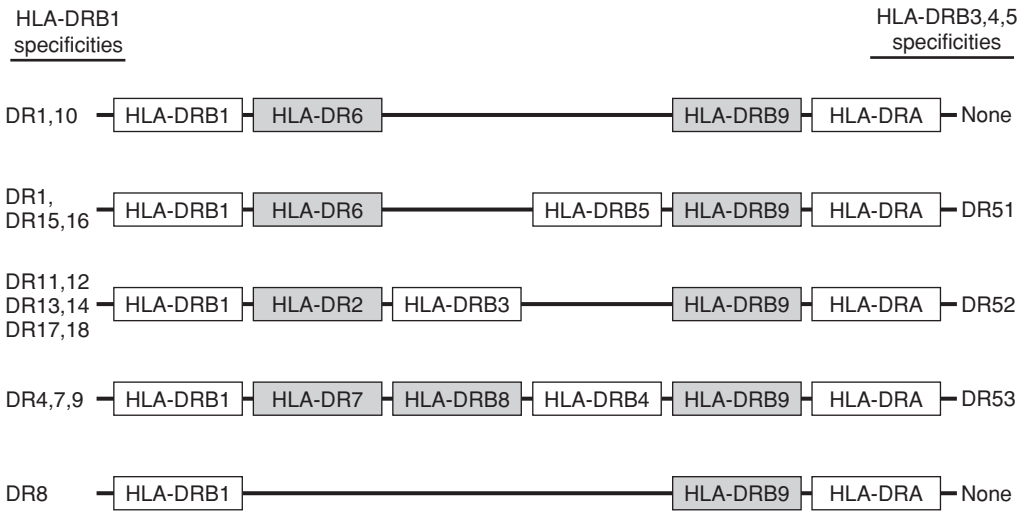

Figure 10–3 Organization of HLA-DRB genes and pseudogenes in DRB haplotypes. The *white boxes* represent expressed HLA-DRB gene and the *gray boxes* pseudogenes.

There are 5 isotypes of the class II molecules, which are designated as HLA-DM, HLA-DO, HLA-DP, HLA-DQ, and HLA-DR. Within the class II region of the MHC, the α and β genes encoding most of the isotypes are organized as pairs of α and β chains that contribute to the same isotype. The genes encoding the α chains are designated as A and those encoding the β chain B. The HLA-DM molecules are the product of HLA-DMA and HLA-DMB, HLA-DO of HLA-DOA and HLA-DOB, HLA-DP of HLA-DPA1 and HLA-DPB1, and HLA-DQ of DQA1 and DQB1 genes, respectively.

There are several HLA class II pseudogenes that are not expressed. There is one HLA-DPA pseudogene, HLA-DPA2, and one HLA-DPB pseudogene, HLA-DPB2. There is also one HLA-DQA pseudogene, HLA-DQA2, and two HLA-DQB pseudogenes, HLA-DQB2 and HLA-DQB3.

The expression of HLA-DR molecules is more complicated than the expression of the other HLA class II molecules. All HLA-DR α chains are encoded by the same DRA gene, HLA-DRA1. However, there are several functional HLA-DRB genes that encode the HLA-DR β chains and several HLA-DRB pseudogenes. In addition, the number of HLA-DRB genes and pseudogenes present varies among individuals. The different combinations of HLA-DRB genes are known as *DRB haplotypes;* several different haplotypes have been described. The HLA-DR molecules can use alleles coded by the DRB1, DRB3, DRB4, or DRB5 genes for β chains. HLA-DRB2, HLA-DRB6, HLA-DRB7, HLA-DRB8, and HLA-DRB9 are pseudogenes. The HLA-DRB1 gene and HLA-DRB9 pseudogene loci are expressed in all HLA haplotypes. At most one other HLA-DRB gene is present in each of the five haplotypes. Some haplotypes have no functional DRB genes other than DRB1 (DR8 and DR10 haplotypes). The other haplotypes have DRB1 plus one of the other three functional DRB genes: DRB3, DRB4, or DRB5 (Fig. 10–3).[2]

HLA Gene Inheritance and Linkage Disequilibrium

Because of their proximity within a short chromosomal distance, HLA genes are inherited en bloc from each parent unless a recombinant event occurs. Thus, each HLA haplotype behaves as a unit and is transmitted through generations according to mendelian principles. Because each individual inherits two of four possible haplotypes (two from each parent), there are four possible genotypes for each individual and the probability of genotypic identity between two siblings is 25% (Fig. 10–4). Because HLA genes are inherited as haplotypes, most HLA phenotypically identical siblings are also HLA genotypically identical. In 2% of cases, recombinant HLA haplotypes (a set of genes derived partially from two chromosomes through recombination) yield genotypes that deviate from this rule.

In large populations gene frequencies achieve equilibrium within a few generations unless selective pressure influences individuals' survival and mating capacity (Hardy-Weinberg law). In equilibrium, gene prevalence is maintained based solely on its frequency. However, within specific populations the presence of specific combinations of HLA antigens occurs with a higher frequency than expected from the prevalence of

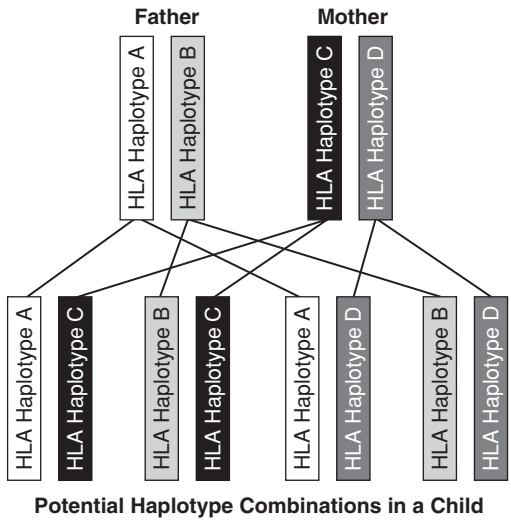

Figure 10–4 Potential HLA haplotypes inherited from two parents. Because four different haplotype combinations are possible, the chances that any two siblings will inherit the same HLA haplotyes and be an HLA "identical" match are 1 in 4.

individual alleles within the same population. This association of specific antigens as HLA haplotypes is called *linkage disequilibrium* and is due to the close proximity of class I and class II on chromosome 6.

Assuming that there were 414, 728, and 210 alleles for the HLA-A, HLA-B, and HLA-C loci, respectively (number of alleles known when this example was described[8]), then theoretically $414 \times 728 \times 210 = 63{,}292{,}320$ HLA class I allelic combinations or haplotypes would be possible. The addition of HLA class II genes to these calculations yields an astronomical number of combinations, making unlikely the identification of two HLA-matched individuals. However, some individual alleles occur with high frequency and are predominant in certain populations (i.e., HLA-A2 in whites and HLA-A24 or HLA-A11 in Asians).[9] Because predominant alleles are often associated with other high-frequency alleles in related haplotypes, the chances of identifying matched individuals are much higher than theoretically possible.

Structure of HLA Class I and II Molecules

Although the genetics of the HLA class I and II molecules differ, the HLA class I and class II protein products are structurally similar. The structure of HLA molecules and their relationship with their natural ligand, the TCR, has been well characterized by crystallography.[10–12] HLA molecules are heterodimer glycoproteins belonging to the immunoglobulin superfamily. Several features are common to all HLA molecules (Fig. 10–5), including two α-helical domains protruding toward the extracellular milieu. Class I molecules consist of two chains: a heavy or α chain and a light chain, β_2-microglobulin. The α chain has a transmembrane portion, but β_2-microglobulin does not. The extracellular portion of the α chain contains three α-helical domains and that of β_2-microglobulin a single α-helical domain (Fig. 10–6). Class II molecules consist of two chains, α and β, both of which consists of two α-helical domains and a transmembrane portion (see Fig. 10–6).

The two outer α–helical domains of both HLA class I and class II form the peptide-binding groove, and they contain the regions with the most amino acid variability. Between the two outer α–helical domains lies a flat surface formed by β-sheet structures that contributes to the formation of a groove that accommodates peptides generated from intracellular (HLA class I) or extracellular proteins (HLA class II) (Fig. 10–7). After a peptide binds to this groove, the helixes–peptide complex is exposed for TCR recognition and receptor activation.

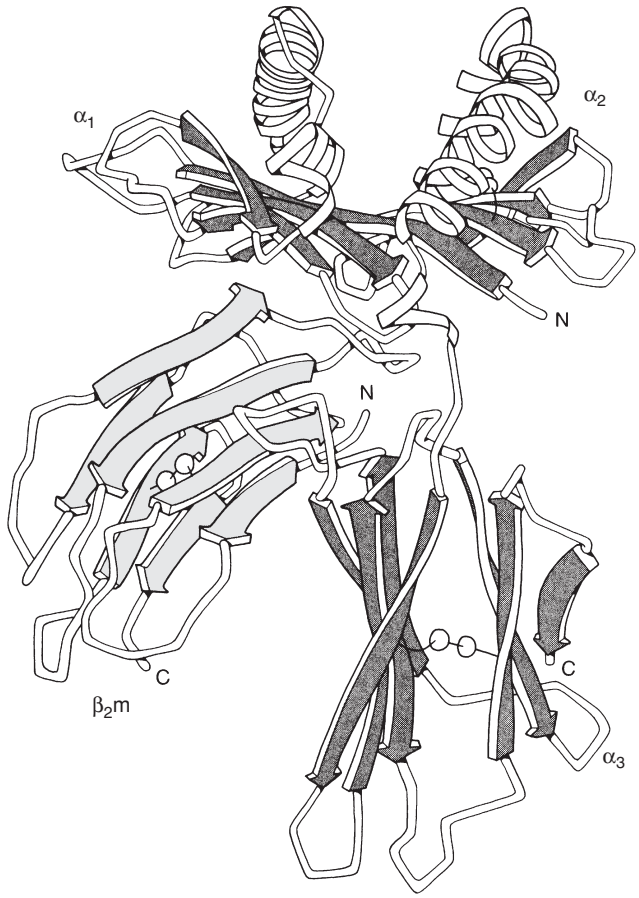

Figure 10–5 Three-dimensional configuration of HLA-A2, modeled from x-ray crystallographic studies. (From Bjorkman PJ, Saper MA, Samraoui B, et al. Structure of the human class I histocompatibility antigen, HLA-A2. Nature 1987;329:506–512.)

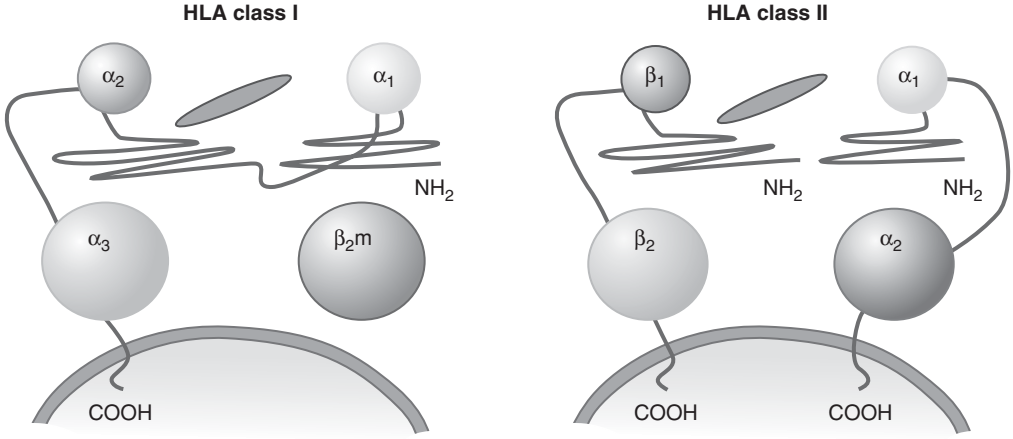

Figure 10–6 Schematic diagram of HLA class I and class II molecules, pointing to their structural similarity. In both HLA classes two immunoglobulin-type domains reside close to the cell membrane (α_3 and β_2 for class I and α_2 and β_2 for class II). The other two domains project toward the extracellular milieu with α-helices (α_1 and α_2 for class I and α_1 and β_1 for class II) and a platform of parallel β-sheets that form a peptide-binding groove. (From Hoffman R, et al. Hematology: Basic Principles and Practice, 4th ed. Philadelphia, Churchill Livingstone, 2005.)

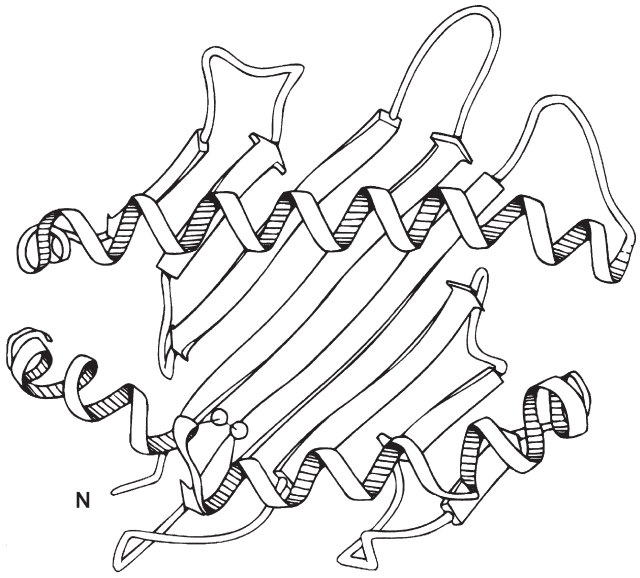

Figure 10–7 Scheme of the peptide groove of an HLA class I molecule, formed by the α_1 and α_2 domains at the side and the β-sheets at the bottom. The view is looking down on the vertically oriented molecule, the T-cell receptor point of view. (From Bjorkman PJ, Saper MA, Samraoui B, et al. Structure of the human class I histocompatibility antigen, HLA-A2. Nature 1987;329:506–512.)

T-cell activation requires the interaction of the TCR with a compatible peptide–HLA molecule complex. The nature of the TCR interaction with the HLA molecule required for productive engagement of the TCR with the HLA–peptide complex spans a surface that includes the peptide and portions of the α and β helixes of the HLA molecule.[12–15] This double requirement of interaction of peptides with both the TCR and HLA complex represents the structural basis for HLA restriction. Because HLA polymorphism is clustered within the α-helices and β-sheet domains that form the peptide-binding groove, specific peptides display a highly variable affinity for distinct HLA alleles.[16,17]

It has been proposed that a given peptide can bind to closely related HLA alleles and as a result HLA superfamilies with similar binding characteristics exist.[18–20] However, peptide binding to related but distinct HLA alleles is associated with conformational dissimilarity due to differential interaction with variant residues in the binding groove.[21] Degenerate and promiscuous TCR recognition of peptides presented by distinct HLA alleles within the same superfamily has also been described.[22] Although the concept of HLA superfamilies holds in general, several exceptions can be expected because single amino acid variants in the HLA molecule may disallow binding of a peptide[23] or may not be permissive to TCR engagement.[24,25]

The binding affinity of a given peptide for an HLA allele can be predicted through computer algorithms that compile available information to identify amino acid residues that fit the distinct pockets of the HLA groove.[16,26] Many of these algorithms supplement this information with experimental testing that analyzes the refolding capability of HLA heavy chains exposed to known peptide sequences in the presence of β_2-microglobulin and/or their dissociation rates (http://bimas.dcrt.nih.gov or http://www.uni-tuebingen.de/uni/kxi). These algorithms are based on the principle that the binding of a peptide to a specific HLA class I molecule promotes stability of the noncovalent assembly of the heavy chain with β_2-microglobulin.[16,27] In addition to using algorithms to predict affinity of specific peptides to a specific HLA molecule, peptide binding can be evaluated directly by elution of peptides from purified HLA heavy chains.[17,28]

In addition to the component of the HLA molecule that is interactive with the TCR, other HLA domains act as coreceptors for the TCR. The association of the CD8+ cytotoxic T cells to the TCR is enhanced by the binding of the CD8 molecule to the α_3 domain of HLA class I, and the association of CD4+ T cells with the TCR is enhanced by the binding of the CD4 molecule to the β_2 domain of HLA class II. Although the coreceptor–TCR interaction is not an absolute requirement, in most cases it determines the HLA class I or II restriction of the individual T cells.[29]

The HLA class I molecules are unique in that the heavy chain and β_2-microglobulin can only be assembled when they are stabilized by a high-affinity peptide derived from the cleavage of intracellular proteins (endogenous pathway of antigen presentation).[6] Most of these intracellular peptides are derived from degradation of self-proteins in the cytosol by proteasomes (psmB) and other proteases.[30] After the proteins are degraded they are assembled into a heavy chain/β_2-microglobulin–peptide complex. To assemble this complex, soluble peptides 9 to 10 amino acids in length are chaperoned into the endosomal compartment by transporter molecules associated with antigen processing (TAP1 and TAP2). While the peptides are in this compartment, they bind to heavy chains according to their amino acid sequence and the individual's HLA type. The binding and stability of the HLA–peptide complex is dependent on the affinity of each peptide for a particular allele. If the stability is sufficient, the peptide-loaded HLA molecule migrates to the cell surface.

In addition to self-peptides, intracellular pathogens produce proteins that are degraded by proteasomes into peptides that compete with the self-peptides for HLA class I molecule-binding sites. Thus, the function of the endogenous pathway of antigen presentation is to provide information to the extracellular compartment of intracellular events. In physiologic conditions, only self-peptides are presented and, therefore, minimal interactions occur with circulating T cells. During infection, pathogen-derived peptides are presented and signal cellular infection to T cells, but antibodies that cannot cross the cell membrane remain insensitive to intracellular pathogens.

Several pathogens such as cytomegalovirus (CMV) can interfere with peptide processing by reducing the density of HLA–/peptide complexes on the cell surface and, consequently, diminish T-cell recognition.[31,32] This escape mechanism can be counteracted by the host through increased susceptibility of virally infected cells to NK cell-mediated cytolysis.[33] Reciprocally, viruses can evade NK cells and escape the recognition by modulating HLA expression.[34–36]

HLA class II molecules bind longer peptides derived from the metabolism of molecules endocytosed from the extracellular compartment. This is known as the *exogenous pathway of antigen presentation.*[6] This is a specialized process used by professional antigen-presenting cells such as macrophages and dendritic cells. HLA class II molecules are assembled within the endosomal compartment, where they are composed of a heterotrimer, including the α and β chains plus a short invariant chain that stabilizes the molecule by occupying its groove while chaperoning its migration to the endosomal compartment (MHC class II peptide-loading compartment, MIIC) where exogenous antigens are processed.

On entering the MIIC, the pre-HLA class II complex is degraded and antigenic peptides are loaded with the help of the nonclassical HLA-DM molecule.[37] On uptake of an exogenous antigen by the HLA class II molecule the antigen peptide undergoes limited proteolysis in the membrane-bound acidic endosomal compartment.

Expression of HLA Molecules

Although there are genetic and structural differences between HLA class I and class II molecules, there are striking functional differences between these two molecules because their expression varies greatly. HLA class I molecules are expressed by most nucleated cells with the exception of germinal cells; HLA class II molecules are expressed mainly by specialized antigen-presenting cells.[38,39] HLA class I molecules are also expressed by platelets[40] and are responsible for refractoriness after multiple transfusion.[41–44] HLA class I molecules are also expressed weakly, though significantly, by reticulocytes and can be the targets of alloantibodies during hemolytic transfusion reactions.[45,46] HLA class II proteins are expressed constitutively by cells associated with the initiation of the immune response, such as monocytes, macrophages, and B cells,[46] and by immune cells activated by cytokines during inflammation. HLA class II molecules initiate immune responses by taking up pathogen components and presenting them to CD4+ helper T cells that in turn initiate humoral immune responses and facilitate cellular immune responses.

The expression of HLA alleles is sensitive to environmental conditions and can be modulated by cytokines, especially interferons.[47] This is particularly important for HLA-B and HLA-C molecules, which are normally expressed at a lower density than HLA-A.[48,49] In addition, HLA class II molecules can be expressed by most cells following cytokine stimulation.[50,51] This might explain why chronic inflammation induced by alloreactions during graft-versus-host disease (GVHD) may facilitate the presentation of tumor-specific antigens by tumor cells with consequent development of graft-versus-neoplasia (GVN) effect. In addition, it might explain how systemic administration of pro-inflammatory cytokines such as interleukin-2 (IL-2) may stimulate immune responses by increasing the antigen-presenting ability of cells within the tumor microenvironment.[52]

HLA Polymorphism and Its Clinical Significance

A striking characteristic of the HLA system is its extreme polymorphism. By chance, most individuals are heterozygous and therefore carry two different alleles for each HLA gene that, being codominant, are equally expressed on the cell surface. As everybody carries three HLA class I (-A, -B, and -C) and three HLA class II (-DR, -DQ, and -DP) genes, most individuals (with the exception of homozygotes) express six different HLA class I and six different HLA class II molecules on the surface of their cells. This has important functional implications because HLA polymorphism is clustered in domains of the HLA molecule that are associated with peptide binding and interactions with the TCR. Thus, most individuals have a broad repertoire of molecules capable of presenting different pathogen components to immune cells. It is, therefore, believed that HLA polymorphism improves a given species' chances of surviving infectious agents.[53] This paradigm is difficult to demonstrate in human pathology, in which the natural history of infectious diseases rarely correlates with HLA phenotype. An exception is the strong association between HLA-B*5701 and lack of progression to AIDS of HIV-infected individuals.[54] Associations have been observed between HLA phenotype and predisposition for Epstein-Barr virus (EBV)-associated nasopharyngeal carcinoma.[55,56] This is of particular interest because nasopharyngeal carcinoma is a virally induced cancer against which T cells may mediate immune surveillance. HLA associations have also been described with less consistency for other virally driven tumors such as cervical carcinoma[57] or immunogenic tumors such as melanoma.[58,59]

HLA polymorphism is at the basis of alloimmunization because most individuals are likely to have different HLA molecules on the surface of their cells. Hundreds of HLA alleles have been identified through high-resolution typing, making the chances that two individuals have identical HLA phenotypes extremely low. The complete and partial mismatches that exist between almost all individuals are at the basis of hyperacute, acute, and chronic rejection of transplanted organs and tissues. Hyperacute rejection is due to preformed antibodies that are directed against donor HLA alleles and usually a result of presensitization of the transplant recipient by multiple transfusions.[60] Acute and chronic rejection result from a combination of humoral and cellular immune reactivity toward donor HLA alleles.[61,62] In addition to allosensitization, HLA alleles can mediate GVHD, whereby hematopoietic cells derived from the grafted organs recognize and reject the host tissues by identifying polymorphisms of intracellular proteins of the host (minor histocompatiblity antigens) presented in association with donor–recipient-matched HLA alleles.

Nonclassical MHC and MHC Class I and Class II Related Molecules

In addition to the genes that encode the α chains of the class I HLA-A, HLA-B, and HLA-C molecules, the class I region of the MHC also encodes the nonclassical HLA-E, HLA-F, and HLA-G molecules. These selectively expressed class I genes are also known as MHC-1b.[63,64] These molecules are characterized by unique patterns of transcription, protein structure, and immunologic function.[65]

The class I MHC region also includes two other genes that are structurely but not functionally related to the HLA genes: MIC and HFE. Several other genes have a structure that is related to the class I genes but are encoded outsided the MHC region. These include the CD1 gene family and MR1(HALs) on chromosome 1, the FCGRT gene on chromosome 19, and zince α_2-glycoprotein on chromosome 7. In addition to the classical HLA-DP, HLA-DQ, and HLA-DR molecules, the class II MHC region encodes the nonclassical HLA-DM and HLA-DO molecules.

HLA-E, HLA-F, and HLA-G

HLA-G is characterized by low polymorphism, and its expression differs from the expression of the classical class I molecules. "Aberrant" cytokine-responsive regulatory sequences[66,67] may be responsible for low levels of HLA-G expression in a variety of human tissues[68] and for the predominant expression of HLA-G by trophoblasts that, in turn, do not express other HLA molecules.[69] Lack of responsiveness of expression to common immune stimulatory pathways (NF-*k*B, interferon-γ, or CIITA) is most pronounced for HLA-G molecules, although this characteristic is shared

by other nonclassical MHC such as HLA-E.[70] HLA-G is also expressed in a variety of cancers. The importance of HLA-G expression by specific cell types is not known because HLA-G can be expressed in various membrane-bound or soluble isoforms with distinct functional characteristics. Functional HLA-G isoforms that include the α_1 and α_2 domains bind and present peptides derived from cytoplasmic proteins.[71] Because of the minimal polymorphism of HLA-G, the repertoire of peptides presented by HLA-G is likely to be limited, suggesting that peptide binding is necessary to stabilize the HLA-G molecule rather than being involved in antigen presentation.

Functionally, HLA-G is thought to modulate the function of NK cells through interactions with their inhibitory receptors.[72] In addition, the HLA-G leader sequence contains a peptide that can bind and stabilize the expression of HLA-E, which also inhibits NK cells.[73] Because the HLA-G derived leader peptide has the strongest affinity for HLA-E among all HLA class I molecules, it is likely that HLA-G is a powerful direct and indirect inhibitor of NK cells that is capable of reducing the risk of cardiac rejection or inducing immune escape of cancer cells.[74] Although much has been published about the immune regulatory role of HLA-G, its true function remains uncertain, principally due to discordant findings reported by various groups.[66]

HLA-E is minimally polymorphic,[3] binds hydrophobic peptides from other HLA class I leader sequences, and interacts with CD94/NKG2 lectin-like receptors present predominantly on NK cells and partially on CD8+ T cells.[75–78] The binding of peptides derived from leader sequences is highly specific and stabilizes the HLA-E molecule, allowing its migration to the cell surface. Thus, the surface density of HLA-E is an indirect reflection of the number of HLA class I alleles expressed by a cell.[79] The interaction of HLA-E with CD94/NKG2 protects HLA-E expressing cells from NK cell killing. Cells damaged by viral infection or neoplastic degeneration may lose HLA class I expression. As a backup mechanism of host protection, reduced HLA class I expression leads to decreased expression of HLA-E, leading to vulnerability to NK cells.[80] Interestingly, some viruses express mimic peptides that bind and stabilize HLA-E so that, while classical MHC molecules are downregulated, HLA-E expression is maintained, allowing the pathogen to simultaneously escape CD8+ T-cell and NK cell killing.[81]

The function of HLA-F remains enigmatic. Its transcriptional regulation is closest to classical HLA molecules because it can be induced by NF-*k*B, interferon regulatory factor-1, and class II transactivator.[82] However, contrary to the classical HLA molecules HLA-F is predominantly empty, mostly intracellular, and has a restricted pattern of expression.[83] Its tissue distribution appears to be limited to B cells; therefore, it is mostly found in lymphatic organs.[83] Structural studies suggest that HLA-F is a peptide-binding molecule, and it may reach the cell surface under favorable conditions when a suitable peptide is present.[84] Once on the cell surface, HLA-F may interact with the effector cell receptors ILT2 and ILT4 as suggested by HLA-F tetrameric complex-binding studies.[84] Thus, it is possible that in specific yet unknown conditions, HLA-F may modulate the function of immune effector cells similarly to HLA-E and HLA-G.

Other Class I and Class II MHC–Related Genes

The class I MHC–related chain genes MIC-A and MIC-B are located within the MHC region and are characterized by high polymorphism (more than 50 alleles so far identified). The molecules encoded by these genes do not appear to bind peptides nor to associate with β_2-microglobulin. Their polymorphic variants are not concentrated around the peptide-binding groove, yet they seem to have functional significance because most of the mutations are nonsynonymous, suggesting selective pressure as driving force. Their tissue distribution is restricted to epithelial cells, endothelial cells, and fibroblasts. It appears that MIC genes modulate the function of NK and CD8+ T cells by binding the NKG2D-stimulating receptor.[85] MIC has also been implicated in transplant rejection; alloantibodies against them are often found in transplant recipients. The alloantibodies may exert complement-mediated cytotoxicity against endothelial cells from the graft.

Other "unusual" MHC-like molecules are present in the genome and have disparate functions, including presentation of lipid antigens (CD1), transport of immunoglobulins (Fc receptor), and regulation of iron metabolism (hemochromatosis gene product).[86] Contrary to classical class I MHC genes, which are constitutively expressed, nonclassical MHC and MIC gene expression depends on stimulation by pro-inflammatory cytokines.[87]

In addition, two nonclassical class II MHC proteins (HLA-DM and HLA-DO) have been described that function as mediators of peptide exchange by stabilizing empty class II MHC molecules.[37] Finally, it is possible that several nonclassical MHC molecules whose function is to present peptides to lymphocytes may be present throughout the genome. Because of their limited polymorphism, however, these genes may have evolved to serve specialized presentation functions.[88]

Non-HLA Polymorphism and Its Clinical Significance

This chapter would be incomplete without mentioning polymorphisms of several other important immune modulators. The significance of these non-HLA polymorphisms is evidenced by the development of GVHD in the presence of HLA identical matching among relatives. Three general areas of polymorphism being investigated are NK cell receptor genes, minor histocompatibility antigens, and cytokines.

During the past decade much progress has been made in identifying the mechanisms of action of NK cells. A major breakthrough was the discovery of HLA class I–specific inhibitory receptors and the role that they play in the regulation of NK function, with consequent effects on the eradication of hematologic malignancies and on prevention of graft rejection and the induction of GVHD.[89] NK cells recognize HLA molecules via killer cell immunoglobulin-like receptors (KIRs), and as a consequence they kill target cells that have lost HLA molecule expression. KIRs are glycoproteins encoded by a compact family of at least 17 different genes located on chromosome 19q13.4 in the lymphocyte receptor complex.[90] All human KIR genes derive from a gene encoding three immunoglobulin (Ig)-like domains (D0, D1, and D2) and a long cytoplasmic tail. However, the KIR genes are diverse and may encode either two or three Ig-like domains and either a long or short cytoplasmic tail (Table 10–1). The long cytoplasmic tails contain one or two immunoreceptor tyrosine-based inhibition motifs (ITIM).[91] KIR molecules with long cytoplasmic tails inhibit NK cytotoxicity; those with short tails do not. The names given to KIR genes are based on the molecule that they encode. The

Table 10–1 **Structural Features and HLA Class I Alleles Recognized by Different Killer Immunoglobulin-like Receptors (KIR)**

KIR	Type of Ig-like Domain	Type of Intracellular Chain	Ligand
KIR2DL1	D1, D2	Long with 2 ITIMs	HLA-C^{Lys80}
KIR2DL2,3	D1, D2	Long with 2 ITIMs	HLA-C^{Asn80}
KIR2DS1	D1, D2	Short	HLA-C^{Lys80}
KIR2DS2	D1, D2	Short	HLA-C^{Asn80}
KIR2DS3,5	D1, D2	Short	Unknown
KIR2DS4	D1, D2	Short	Unknown
KIR2DL4	D0, D2	Long with 1 ITIM	HLA-G
KIR2DL5A/B	D0, D2	Long with 1 ITIM	Unknown
KIR3DL1	D0, D1, D2	Long with 2 ITIMs	HLA-B^{Bw4}
KIR3DL2	D0, D1, D2	Long with 2 ITIMs	HLA-A
KIR3DL3	D0, D1, D2	Long with 2 ITIMs	
KIR3DS1	D0, D1, D2	Short	Unknown

ITIM, immunoreceptor tyrosine inhibitory motif.

first digit corresponds to the number of Ig-like domains in the molecule and a "D" denotes *domain*. The D is followed by either an "L" for *long* cytoplasmic tail, S for *short* cytoplasmic tail, or "p" for a *pseudogene*. The last digit indicates the number of the KIR gene.[92]

Expression of KIR in individual NK cells is complex because NK cells may express several members of the KIR family. The number of KIR genes in each haplotype varies among individuals. The most common haplotype, known as group A, is made up of 6 genes (2DL1, 2DL2 or 2DL3, 3DL1, 3DL2, 2DS4, and 2DL4). Various KIR genes can recognize different HLA-A, HLA-B, and HLA-C molecules. HLA-C antigens can be divided into two groups based on polymorphisms at amino acid positions 77 and 80 of their class I heavy chains. One group has asparagine (Asn) at position 77 and lysine (Lys) at 80; the other has serine (Ser) at 77 and Asn at 80. Some KIRs recognize HLA-C antigens with Asn77 and Lys80; other KIRs recognize HLA-C antigens with Ser77 and Lys80. The polymorphism at position 80 is most important. Another group of KIRs reacts with HLA-B antigens that carry specific combinations of amino acids at positions 77 and 83 of the heavy chain that form HLA-Bw4. KIR recognition of HLA class I molecules is degenerate because a single KIR can interact with multiple HLA class I alleles. Another NK inhibitory receptor (CD94-NKG2A) recognizes the nonclassical HLA-E molecule. In addition, each of the KIR genes is extensively polymorphic.

Because the genes for KIR, HLA, and CD94-NKG2A are located in separate chromosomes, they segregate independently; consequently, individuals may carry genes for KIRs for which there is no correspondent HLA ligand.[93] Because HLA-E is expressed in all individuals, NK cells that bear the CD94-NKG2A receptor are not alloreactive. Because the specificity of KIRs for their ligands is broad and each individual carries several KIRs, it is likely that in the majority of cases all NK cells of a given person express at least one KIR that is specific for a self-HLA class I allele. Thus, in autologous settings NK cells kill only aberrant cells that have lost HLA class I expression. In contrast, NK cells can kill allogeneic cells that do not express HLA class I alleles recognized by their KIR. Thus, by knowing the KIR repertoire of a given transplant recipient and the HLA type of the donor, it is theoretically possible to predict the likelihood of an NK-mediated alloreaction. Importantly, it appears that "alloreactive" NK cells undergo proliferation on exposure to stimulatory cells; therefore, they can preferentially expand in the presence of allogeneic tissue.

NK cells also express activating receptors that are responsible for their lytic activity. These activating receptors include KIRs with short cytoplasmic tails. Although the ligands for these activating receptors have not been identified, it is possible that they are expressed primarily by activated or proliferating cells. It is, therefore, possible that during the inflammatory process induced in allogeneic conditions, normal cells may become activated by cytokines and express ligands responsible for NK activation in the absence of HLA class I molecules reactive with the inhibitory receptors.[89]

The relevance of KIR in haploidentical hematopoietic transplantation has been well studied. In haploidentical transplants several KIR–HLA class I allele combinations are possible, including NK cells from the graft that express KIR but do not interact with the donor's HLA molecules (graft-versus-host alloreactivity) and NK cells from the donor that do not interact with the host's HLA molecules (graft rejection alloreactivity). The presence of graft-versus-host reactive NK cells due to incompatibilities between donor and recipient (especially HLA-Cw families) has favorable effects in the outcome of acute myeloid leukemia.[94] Alternatively, a good match may be present between graft NK cells and host's HLA and between host's NK cells and graft HLA. In such a case no alloreactivity will occur. If the stem cell donor is incompatible with the host's NK cell repertoire, the host's reactivity may lead to graft rejection. Interestingly, alloreactive grafted NK cells seem to prevent GVHD while inducing GVN.[89]

Like HLA, KIR genes are polymorphic, and their variability is clustered in positions likely to impact the overall structure of the molecule. The relevance of KIR gene polymorphism in the outcome of bone marrow transplantation (BMT) is unclear. It appears that the risk of GVHD is highest in the context of unrelated BMT when the recipient KIR genotype is "included" in the donor KIR genotype.[95] These results show that compatibility between KIR genotypes themselves may influence the outcome of BMT.

Minor histocompatibility antigens (mHA) are polymorphic molecules whose peptides contain variant sequences that are presented by HLA alleles. They have been shown to be targets of cytotoxic T lymphocytes that can lyse leukemia cells.[96] In addition, some mHA are selectively expressed by neoplastic cells.[97] At present little is known about the identity of mHA epitopes in the context of

various HLA types and their significance in the development of GVHD and GVN.

Cytokines are another large family of molecules associated with antigen recognition, graft rejection, and GVHD. Their polymorphism is becoming an important area of investigation in the context of transplantation, autoimmunity, and cancer. Generally, polymorphic sites of cytokines reside in regulatory regions so that genetic variants are associated with high or low production of a given cytokine rather than differences in its function. Information about cytokine polymorphism is being compiled on a website (http://www.bris.ac.uk/Depts/PathAndMicro/services/GAT/cytokinet.htm). Although no consensus has been achieved yet, several studies have shown associations between various cytokine genotypes and propensity to disease or transplant outcome. Interestingly, a strong association has recently been noted between a low IL-10 production genotype and a tendency to develop melanoma and prostate cancer.[98,99]

HLA Nomenclature

The HLA system nomenclature[100] began as HL-A for human leukocyte locus A. With the recognition that HLA molecules are encoded by more than one locus, the A came to represent *antigen* and a locus designation was added after HLA (i.e., HLA-A, HLA-B, HLA-C, HLA-D).[8] The WHO has taken responsibility for updating the nomenclature; the most recent update was in 2004 following the 14th International Histocompatibility Workshop.[3] At present, two nomenclature systems are used. An immunologically defined nomenclature is based on the identification of HLA antigens on the surface of leukocytes. HLA phenotypes described by immunologic methods are, therefore, conventionally called *HLA antigens.*[101] The second system is based on the molecular identification of nucleotide sequences in genomic DNA; the results are conventionally referred to as *HLA alleles*. Because molecular typing has higher resolution, this nomenclature has gained widespread acceptance.

Immunologically Defined HLA Nomenclature

Immunologically defined nomenclature follows this convention: HLA is separated by a hyphen from a capital letter identifying the locus encoding distinct HLA class I (-A, -B, -C) or class II (-DR, -DQ, -DP) antigens. The letter is followed by a number that identifies a serologic family of alleles sharing epitopes recognized by alloantibodies or alloreactive cytotoxic T cells. With improved understanding of the molecular genetics of the HLA region, various appendages have been removed from the HLA nomenclature. For instance, the letter *w* was used to indicate a provisional assignment; this has been discontinued, although it is occasionally added to HLA-C antigen nomenclature to distinguish it from complement genes. HLA-DP and HLA-DW also maintained this letter to reinforce the dependency of their immune identification predominantly through cellular techniques. Finally, HLA-Bw4 and HLA-Bw6 retain the *w* to emphasize that these public epitopes are shared by several HLA-B and some HLA antigens.

Sequence-defined Allelic Nomenclature

Recently, a bridge between immunologic and molecular nomenclature has been proposed whereby HLA antigens that encompass a single gene product can be attributed a two-digit numeric extension corresponding to the molecular nomenclature for that allele.[102] The 10th International Histocompatibility Workshop recommended a sequence-based nomenclature in 1987[102] to describe alleles not distinguishable by immunologic methods. Since then, the number of HLA alleles has rapidly increased. A total of 422 new alleles were named between the previous report in 2003 and December 2004[3]: 349 designations were given to HLA-A, 627 to HLA-B, and 182 to HLA-Cw alleles (1180 named HLA class I alleles). Assignments for HLA class II included 394 HLA-DRB1, 61 HLA-DQB1, and 116 HLA-DPB1 alleles. Other designations are summarized in Table 10–2. In this nomenclature system HLA designates molecules belonging to the human MHC followed by the locus (i.e., -A, -B). Alleles are then identified after an asterisk (*). A four-digit number is used in which the first two digits refer to the original serologic family (i.e., HLA-A2 serologic would be HLA-A*02). The last two digits designate alleles sequentially identified within that family. Often numbers are missing because an original assignment was revoked (this is why there is no HLA-A*2401 allele). When silent mutations are identified (variations in nucleotide sequences that do not translate into changes in amino acid sequence), the name of the allele remains identical, but another two digits are added to designate that it is a variant that has no functional significance. When new sequences are identified they are submitted to EMBL (www.ebi.ac.uk/Submissions/index.html) GeneBank (www.ncbi.nlm.nih.gov/Genbank/index.html), or DDBJ (http://www.ddbj.nig.ac.jp/sub-e.html).

The requirements for new allele naming were described by Marsh and colleagues.[103] The WHO committee also made recommendations about the naming of alleles with aberrant expression, such as HLA-G isoforms and KIRs. Some alleles are identifiable at the genomic level, but they are not translated into protein (pseudogenes) and are indicated by the addition of an N (for *null*) following the numerical designation of the allele. Mutations inducing a reduction of expression are marked by L (for *low expression*). An "S" denotes alleles expressed as *soluble* or *secreted* molecules; such molecules, such as HLA-B*4402010S, are characterized by an intronic variant that disallows the expression of the transmembrane domain of the HLA molecule and therefore only exists in a soluble form. Differential splicing of HLA-G leads to production of membrane-bound and soluble forms, which are denoted by a lowercase "m" or "s," respectively, before HLA. Limited cytoplasmic expression is denoted by "C," and aberrant expression by "A." Finally, KIR polymorphism will be classified by a new system that is in preparation.[93,103,104] A nomenclature system for cytokine polymorphism has not been developed yet.[105]

HLA Typing in Transfusion Medicine and Determination of Compatibility

HLA Typing

Originally, HLA phenotyping was used to support transplantation and transfusion needs with the purpose of identifying the best match between donors and recipients. Allosensitization of recipients previously exposed to heterologous cell products was tested by identifying alloreactive antibodies in serum. Crossmatch procedures involving serum from alloimmunized patients and cells from donors were performed to grade compatibility of candidate donor–recipient pairs.

Table 10–2 **Name of Genes in the HLA Region Considered by the WHO Nomenclature Committee and Numbers of Named Alleles[3]**

Name	Previous Equivalents	Molecular Characteristics	No. of Alleles (Dec. 2004)
HLA-A	—	Class I α-chain	349
HLA-B	—	Class I α-chain	627
HLA-B	—	Class I α-chain	182
HLA-E	E, '6.2'	Associated with class I 6.2-kB Hind III fragment	5
HLA-F	F, '5.4'	Associated with class I 5.4-kB Hind III fragment	2
HLA-G	G, '6.0'	Associated with class I 6.0-kB Hind III fragment	15
HLA-H	H, AR, '12.4', HLA-54	Pseudogene assoc. with class I 5.4-kb Hind III fragment	
HLA-J	cda 12, HLA-59	Pseudogene assoc. with class I 5.9-kb Hind III fragment	
HLA-K	HLA-70	Pseudogene assoc. with class I 7.0-kb Hind III fragment	
HLA-L	HLA-92	Pseudogene assoc. with class I 9.2-kb Hind III fragment	
HLA-N	HLA-30	Pseudogene assoc. with class I 1.7-kb Hind III fragment	
HLA-S	HLA-17	Pseudogene assoc. with class I 3.0-kb Hind III fragment	
HLA-X	—	Class I gene fragment	
HLA-Z	HLA-Z1	Class I gene fragment located in HLA class II region	
HLA-DRA	DRα	DR α chain	3
HLA-DRB1	DRβI, DR1B	DR β1 determining specificity for DR1, DR2, DR3, etc.	394
HLA-DRB2	DRβII2	Pseudogene with DRβ-like sequence	1
HLA-DRB3	DRβIII, DR3B	DR β3 determining DR52, Dw24, w25, –26 specificity	41
HLA-DRB4	DRβIV, DR4B	DR β4 determining DR53 specificity	13
HLA-DRB5	DRβV, DR5B	DR β5 determining DR52, Dw24, w25, –26 specificity	18
HLA-DRB6	DRBX, DRBσ	Pseudogene found in DR1, DR2, and DR10 haplotypes	3
HLA-DRB7	DRBψ1	Pseudogene found in DR4, DR7, and DR9 haplotypes	2
HLA-DRB8	DRBψ2	Pseudogene found in DR4, DR7, and DR9 haplotypes	1
HLA-DRB9	M 4.2 β exon	Pseudogene isolated fragment	1
HLA-DQA1	DQα1, DQ1A	DQ α chain as expressed	28
HLA-DQB1	DQβ1, DQ1B	DQ β chain as expressed	61
HLA-DQA2	DXα, DQ2A	DQ α-related chain, not known to be expressed	
HLA-DQB2	DXβ, DQ2B	DQ β-related chain, not known to be expressed	
HLA-DQB3	DVβ, DQB3	DQ β-related chain, not known to be expressed	
HLA-DOA	DNA, DZα, DOα	DO α chain	8
HLA-DOB	DOβ	DO β chain	9
HLA-DMA	RING 6	DM α chain	4
HLA-DMB	RING 7	DM β chain	7
HLA-DPA1	DPα1, DP1A	DP α chain as expressed	22
HLA-DPB1	DPβ1, DP1B	DQ β chain as expressed	116
HLA-DPA2	DPα2, DP2A	DP α chain-related pseudogene	
HLA-DPA3	DPA 3	DP α chain-related pseudogene	
HLA-DPB2	DPβ2, DP2B	DP β chain-related pseudogene	
TAP1	ABCB2, RING4	ABC (ATP-binding cassette) transporter	7
TAP2	ABCB3, RING 11	ABC (ATP-binding cassette) transporter	4
PSMB9	LMP2, RING 12	Proteasome-related sequence	
PSMB8	LMP7, RING 10	Proteasome-related sequence	
MICA	PERB 11.1	Class I chain-related gene	57
MICB	PERB 11.2	Class I chain-related gene	18
MICC	PERB 11.3	Class I chain-related gene	
MICD	PERB 11.4	Class I chain-related gene	
MICE	PERB 11.5	Class I chain-related gene	

HLA phenotyping has also been applied to identify links between a given disease and the genetic makeup of its carriers.[106] Strong associations are exemplified by birdshot uveitis, a disease occurring exclusively in HLA-A29 individuals[107]; type I diabetes and other autoimmune diseases[108–110]; or long-term survival of HIV-infected individuals.[54] These studies evaluated the role that genetic background may have contributed over environmental factors.[106,111] HLA associations are thought to be due to differential ability of distinct alleles to present immunogenic epitopes[107,108] or to the close linkage of HLA class I and II antigens to the HLA class III region where potent immune modulators such as TNF-α are located.[112]

HLA phenotype associations have also been suggested as predictors of immune responsiveness of cancer to immune therapy.[59] However, such associations have remained difficult to reproduce. Most recently, patient HLA typing is being required before enrollment into immunization protocols[25] because the response to the vaccine may be HLA-restricted. Analysis of specific HLA–epitope combinations for immunization protocols requires high-resolution typing because allelic variations may affect antigen presentation and the immune response to vaccination.[23,113]

Traditional serologic assessment of HLA antibodies and antigens takes advantage of fetomaternal sensitization. In mammals, the progeny carries a full haplotype of paternal origin, and pregnant women may develop antibodies against antigens expressed by the paternal haplotype. Maternal sera are collected at term and characterized by testing their ability to kill HLA-bearing cell lines of known phenotype in the presence of complement (complement-dependent cytotoxicity, or CDC).[114] CDC is then used for HLA typing by exposing circulating cells expressing HLA class I (most cells) and class II (predominantly B cells) antigens from the

individual to be typed to previously characterized alloantisera or monoclonal antibodies.[115]

Traditionally, when sera from sensitized patients are screened for antibodies directed to HLA antigens, a HLA-phenotyped repository of cell lines are used in a CDC assay to identify alloantibodies. The fraction of cell lines killed by the sera serves as a rough grade or indicator of the intensity of allosensitization and is referred to as *panel-reactive antibody (PRA) reactivity*.

Some antibodies activate complement and kill with poor efficiency: the cytotoxicity-negative-absorption-positive (CYNAP) phenomenon.[116] CYNAP may cause the underestimated allosensitization judged by cytotoxicity testing. By modifying CDC with the addition of antihuman antibodies capable of activating complement, CYNAP can be circumvented (augmented CDC). However, with this assay relatively innocuous antibodies may cause overestimation of clinically relevant allosensitization.[117]

Other methods identify alloantibodies, including the immobilization of HLA molecules on solid surface to capture soluble antibodies[118–120] and a flow cytometry method that uses a spectrum of microbeads coated with HLA molecules of known type.[121,122] An interlaboratory comparison of serum screening for HLA antibody determination suggested that enzyme-linked immunosorbent assay (ELISA) and flow cytometry yield higher PRA activity values compared with CDC or augmented CDC.[119] However, the study suggested a lack of consistency among participant laboratories, leaving unsolved which method most accurately defines clinically relevant allosensitization; a panel of various methods may be most informative.

The CDC phenotyping assay is declining in interest in the United States because most laboratories are switching to easier-to-handle and higher-resolution molecular methods. However, cellular immunologic methods remain valuable to characterize functional aspects of HLA molecules because molecular genotyping methods cannot define whether an HLA allele is expressed.[123] Thus, it is likely that immunologic methods will continue to complement molecular methods in the future.[123]

The usefulness of conventional serologic typing has been limited by the availability of allele-specific sera. Most importantly, because antibodies identify structural differences on the surface of HLA molecules, variations caused by nucleotide polymorphism in areas that are not exposed, such as the peptide-binding groove of the HLA heavy chain, are not detectable. However, the differences that are located in the peptide-binding groove are of functional significance because they determine the specificity and affinity of peptide binding[124,125] and T-cell recognition of self and allogeneic target cells.[24,126]

DNA-based typing methods directly determine the sequence of HLA molecules.[127] Various polymerase chain reaction (PCR)-based methods have been described, among which sequence-specific primer (SSP)[127,128] and sequence-specific oligonucleotide probe (SSOP)-based methods[129] are the most universally used. The resolution of SSP and SSOP assays is limited only by the number of allele-specific primers or probes used to identify an ever growing number of alleles (http://www.anthonynolan.com/HIG/index.htm). The realization of the richness of HLA polymorphism has led to a proportional increase in the complexity of the assays utilized to cover all possible alleles. As a consequence, accurate HLA typing for donor and recipient matching in transplantation has become increasingly complex and burdensome. In addition, due to the important role that HLA molecules play in antigen presentation and the stringency of the relationship between epitope and associated HLA allele, high-resolution typing is increasingly requested for appropriate enrollment of patients into immunization protocols aimed at the enhancement of T-cell responses. Therefore, high-resolution HLA typing is increasingly in demand in clinical and experimental settings.

Although oligonucleotide-based methods could theoretically discriminate any known polymorphic site, they have two major limitations. First, they require a specific PCR for each allele investigated. Because each individual has only two alleles for each locus a disproportionately large number of PCRs need to be performed to cover all possible polymorphisms in order to identify the two alleles in the individual tested. In addition, because both oligonucleotide-based methods are based on specific interactions with known oligonucleotide sequences unique to a particular allele, they cannot identify unknown polymorphisms unless, by chance, the variation occurs within the region spanned by one of the oligonucleotide primers or pairs used in the assay. Because of these limitations interest is growing for definitive typing methods that yield conclusive information about the identity of the alleles typed. The most comprehensive method is sequence-based typing (SBT), however, its utilization has been limited by cost of equipment and reagents and by the high level of expertise and time required for the interpretation of each typing. In addition, some of the alleles and allele combinations are difficult to resolve even with SBT.[130] More recently, high-throughput robotic SBT has been developed that allows sequencing of hundreds of genomic fragments each day.[131] Finally, new methods based on high-density array technology are being developed that may allow extensive typing of known and unknown polymorphisms on microchips.[132]

High-resolution HLA genotyping methods yield high-resolution information of an individual's HLA type. The wealth of information is, however, counterbalanced by increased difficulty in identifying suitable HLA alleles during donor–recipient pairing or accrual into immunization protocols restricted to specific HLA–epitope combinations. Thus, at present clinicians are faced with the daunting task of applying high-resolution typing results of unclear relevance to clinical settings.[133]

TESTING FOR ALLOSENSITIZATION AND DETERMINATION OF COMPATIBLE RECIPIENT–DONOR PAIRS

Ideally, any cell containing a human product transfused or transplanted between different individuals should be HLA compatible. Yet, in most cases histocompatibility is not prospectively sought. Thus, patients who have received long-term therapies often become reactive to various antigens, including HLA. Transfusion of leukocyte-depleted products has decreased the incidence of allosensitization, yet organ transplant candidates often develop alloreactivity before the transplant. To prevent rejection in organ transplant recipients alloreactivity must be documented before transplantation. Alloreactive patients can still receive a transplant if the documentation provided states that the donor organ has no mismatched HLA antigens reactive with the patient's antibodies. Similarly, patients who have received repeated platelet transfusions may become allosensitized and consequently

refractory to further transfusions unless platelets from HLA-compatible donors are used.

Obviously, the best compatibility among organ, hematopoietic progenitor cell, and platelet donors and recipients is identical matching. However, particularly in the case of rare HLA types, it is often impossible to identify a perfectly matched unrelated donor. Thus, other strategies have been adopted to identify the best possible match or "compatible mismatch." Selection of compatible unrelated donor–recipient pairs is carried out through typing with serologic, cellular, and molecular methods.[134] With the increasing resolution of these typing methods, the chances of identifying compatible donors based on full or partial HLA matching has become increasingly low.[133] To broaden compatibility-matching criteria for donor–recipient pairs, matching systems have been developed based on shared public epitopes assigned to crossreacting groups (CREGs)[135] or shared amino acid polymorphisms defined through sequence information.[136] Pre-existing alloantibodies further restrict the availability of compatible donors. Highly sensitized recipients with PRA reactivity exceeding 85% of tested specificities represent a particularly challenging group.[137] An alternative approach to the exclusion of alloreactive determinants is the inclusion of "acceptable" antigen mismatches expressed in a panel of cells that give negative reactions with the recipient sera,[138] thereby extending the repertoire of possible donors. Unfortunately, even these tools for the identification of unrelated, partially matched donor–recipient pairs often fail to identify a suitable match.

Recently Duquesnoy[137] described a molecularly based algorithm to identify histocompatible donor–recipient pairs called HLAMatchmaker. This method focuses on the structural basis of HLA class I polymorphism so that compatible HLA mismatches can be identified without extensive serum screening. This algorithm is based on the principle that short amino acid sequences, triplets, characterizing polymorphic sites of the HLA molecules, are the critical components of allosensitizing epitopes. Such amino acids reside in the α-helices and β-loops of the heavy chain. Because each HLA molecule expresses a characteristic string of these determinants, it is possible to characterize each molecule according to the linear sequence of amino acid triplets present on its surface. Based on the reasonable assumption that none of the triplets present in the HLA repertoire of the recipient are self-immunogenic, it is possible through a process of "electronic recombination" to identify donors with HLA alleles different from the recipient's but containing exclusively shared triplets. The selected HLA alleles will be compatible because they do not contain any epitope absent in the recipient.

In theory, a large number of triplets could occur if polymorphisms were randomly distributed. However, most HLA molecules span conserved domains and only a total of 142 different polymorphic triplets designate serologically defined HLA-A, HLA-B, and HLA-C antigens.[137] Triplet polymorphism can occur in 30 locations on HLA-A, 27 in HLA-B, and 19 in HLA-C chains. Because the HLAMatchmaker algorithm includes interlocus comparison, it is possible to accumulate the information into a single database. Among the 142 polymorphic triplets, 29 are polymorphic for one class I locus but monomorphic for another. Such polymorphic triplets cannot be immunogenic because they are always present on the patient's own HLA antigens, whereas the remaining 113 triplets have immunogenic potential. With this algorithm it is possible to significantly broaden the number of "molecularly matched" HLA alleles and therefore significantly increase the chances of identifying a compatible donor, particularly in those cases when the recipient has a rare HLA phenotype.

In addition, if information on the specificity of HLA antibodies in the recipient is known, HLAMatchmaker considers triplets that are present in the panel of screening cells that give negative reactions with the recipient's serum. These negative panel cells can be expected to share antigens with the patients; however, other HLA antigens may be present and contain mismatched triplets that apparently are not immunogenic for that recipient. Such triplets are therefore acceptable and can be added to the algorithm for the identification of possible donors.

Thus, HLAMatchmaker assesses HLA compatibility at a molecular level by determining whether or not a triplet in a given position of a mismatched HLA antigen is also found in the same position in any of the recipient's own HLA-A, HLA-B, and HLA-C molecules. A shared triplet in the same position on a mismatched HLA antigen cannot elicit a specific antibody response in that patient. This hypothesis needs future testing as this strategy might represent a revolutionary tool for the identification of potential donors. Preliminary verification of the algorithm in a series of high PRA renal patients suggested that this is a proper strategy, at least in highly sensitized renal transplant candidates waiting for kidneys from unrelated donors.[139] HLAMatchmaker is also effective at selecting the best HLA-typed platelet component to transfuse to alloimmunized thrombocytopenic patients.[140]

The HLA Molecules as Antigens and HLA Alloimmunization

Because of their high density on the surface of cells HLA molecules can become immunogenic when cells from one individual are exposed to another's immune system. The mechanism(s) leading to HLA allosensitization are believed to follow two pathways. The first pathway is followed during most immune reactions and involves donor antigen uptake by donor antigen-presenting cells and presentation to recipient lymphocytes (indirect pathway). In this case, the donor's HLA molecules are processed into peptides through the exogenous pathway of antigen presentation and presented to recipient T cells as linear peptides.[141,142] This pathway is believed to be responsible for the development of alloantibodies as well as helper T-cell responses, but its role in the development of cytotoxic T-cell responses remains unclear. Because this pathway depends on the presentation of donor HLA molecules by the recipient's HLA alleles, it may explain why the humoral response to HLA class I allodeterminants correlates with the HLA phenotype of the recipient.[143] The indirect pathway of HLA allorecognition has been associated with allograft rejection.[144]

Because the function of HLA molecules is to present antigenic determinants to T cells, it could be easily envisioned how minor changes in their structure could be misinterpreted as antigenic epitopes. Thus, intact HLA molecules residing on the surface of donor cells are a perfect target for T cell–mediated allorecognition (direct pathway) by recipient cells either through direct cytotoxic effect of T cells against

target cells or by the activation of helper T cells, through HLA class II engagement, which leads to stimulation of antibody-mediated immune responses.[145]

Humoral alloresponses mediated most frequently by immunoglobulin M (IgM) are predominant when sensitization involves infrequent allogeneic exposure because they require smaller amounts of antigenic material. T-cell responses become more predominant in the context of transplantation where the persistence of the continuous allogeneic stimulation allows the expansion and sustenance of alloreactive cytotoxic T cells.

Because antibodies and TCR have different requirements for engagement, epitopes recognized by T cells and antibodies are different. Antibodies require interaction with a small structure, including a limited number of amino acids; thus, any amino acid sequence combination on the surface of an HLA allele not present in the individual exposed to the alloreaction may represent an epitope. The TCR has a much lower binding affinity for their ligand and binding requires the complete interaction of the TCR with the antigenic peptide as well as the α– and β–helices of the HLA class I heavy chain.[12] Thus, although several B-cell epitopes recognized by antibodies can be identified in a given HLA molecule, generally the whole HLA molecule is necessary for T cell–dependent allorecognition.

Two types of antibody-defined epitopes can be identified according to their frequency among HLA alleles. Private epitopes are almost, but not totally, unique for each single serologically defined HLA antigen, and antibodies directed to private epitopes are used for phenotyping. Private epitopes are generally shared by all molecularly defined alleles in a given family; for this reason fine differences among alleles within a general family cannot be distinguished serologically. Public epitopes are more widely distributed among serologically defined antigens and have been used to cluster distinct serologic families into groups. Public epitopes have an immune dominant character. Immune sera that identify public epitopes have been considered to be predictive of major CREGs. When donors and recipients belong to the same CREG, alloreactivity is thought to be less likely to develop (Table 10–3). The predictive value of CREG matching of donor–recipient pairs on transplant outcome or platelet transfusion results, however, remains to be demonstrated.

Not all subjects that have been exposed to HLA alloantigens develop alloantibodies and, in fact, exposure to low doses of donor-specific HLA antigens through donor-specific blood transfusions may have a beneficial effect on the survival of organ allografts.[146] Several hypotheses have been proposed for the capriciousness of allosensitization, including presence of regulatory immune responses or cytokine-mediated immune suppression. However, the mechanisms that modulate the quality and quantity of alloimmunity remain elusive; different aspects of this algorithm are discussed ad hoc in this chapter with particular attention to molecularly defined algorithms for the prediction of histocompatibility.[123,137,147,148]

HLA matching enhances the outcome of some types of organ transplants. An analysis of more than 150,000 renal transplant recipients performed by centers participating in the Collaborative Transplant Study showed that a complete mismatch (6 HLA-A+B+DR) had a 17% lower survival expectation than no mismatch ($p < 0.0001$),[149] and matching was particularly beneficial in patients with highly reactive preformed alloantibodies. The same study suggested that high-resolution matching based on molecular typing improved graft survival. Similar results were observed in cardiac transplantation where HLA matching yielded significantly ($p < 0.0001$) better results. This is particularly important because in most centers donor hearts are currently not allocated according to HLA match. HLA matching was not beneficial in liver transplantation.[150]

The induction of donor-specific hyporesponsiveness has been particularly well documented in the context of renal allotransplantation and may limit the need for immune suppression. A recent randomized study suggested that pretransplant donor transfusions improved the survival of cadaver kidney grafts in patients receiving modern immune

Table 10–3 **Population Frequencies of Major Cross-Reactive Groups or Determinants Present on HLA-A and HLA-B Gene Products**

suppressive regimens, although the mechanism remains unclear.[151,152] Thus, although most centers presently do not implement deliberate blood transfusions, the usefulness of this approach needs to be further investigated.

Patients who have been previously exposed to HLA class I expressing heterologous cells and who have produced HLA antibodies often require platelet transfusions. Such patients are refractory to random donor platelets and must be given HLA-matched or "semi-matched" apheresis components.[41–44] However, the provision of HLA-matched platelets does not always improve platelet recovery and survival. Possibly, the ineffectiveness of some "HLA-matched" platelet transfusions is due, at least, in part to unrecognized HLA mismatches between the donor and recipient resulting from low-resolution methods used for typing the donor and recipients. Higher-resolution typing methods have been advocated, but it remains controversial whether molecularly based HLA typing confers an advantage over serologic typing; this principle was recently questioned in the context of hematopoietic cell transplantation.[153,154]

HLA as a Functional Mediator of Graft-versus-Host Disease and/or Graft-versus-Neoplasia Effect

Allogeneic or syngeneic hematopoietic progenitor cell (HPC) transplantation is used to treat hematologic malignancies[155,157]; hematologic disorders such as aplastic anemia,[158] thalassemia,[159] or myelodysplastic syndrome[160]; immune difficiency states; and some types of cancers.[161] The objective of HCP transplantation in malignancies is to cure the patient by eradicating the neoplastic cells with high-dose myeloablative chemotherapy followed by restoration of hematopoiesis through the transplantation of normal hematopoietic stem cells derived from HLA-compatible normal donors. This strategy, however, is characterized by the reaction by the transplanted (donor's) immune system toward the host's normal cells, GVHD.[162,164] The development of GVHD is often associated with an immune reaction that preferentially targets neoplastic cells (the GVN effect).[161,165,171] GVHD and the GVN effect can occur in the presence of a complete HLA match, suggesting that the HLA molecules themselves are not the targets of the allosensitization reaction responsible for GVHD or the GVN effect. Instead cells involved with GVHD and the GVN effect are induced by polymorphic molecules presented by the HLA molecules and expressed by the recipient's cells and recognized by the grafted immune cells.

Graft-versus-Host Disease

Graft-versus-host disease represents the alloimmune reaction of donor lymphocytes against normal cells of the recipient. GVHD occurs predominantly in association with HPC transplantation because HPC transplantation also replaces the host humoral and cellular immune systems. GVHD is a major complication of HPC transplantation but for a successful transplant a fine balance must be maintained between GVHD and graft rejection by modulating the level of post-transplant immune suppression.[169] In addition, other major events associated with HPC transplantaion, such as post-transplant infection, leukemic or tumor relapse, and other regimen-related mortalities, are strongly influenced by the methods use to treat GVHD.

T-cell depletion has been advocated as a means of preventing GVHD by decreasing the probability of cellular and humoral alloresponses.[172,173] This strategy decreases the occurrence of GVHD but is associated with an increased risk of graft rejection and tumor/leukemia relapse.[174] In fact, Weiden and colleagues[175] observed that survivors of severe acute GVHD had a significantly lower incidence of tumor relapse compared with patients who did not experience GVHD. This association appeared mandatory and it was felt that the beneficial GVN effect was inseparable from GVHD.

The risk of GVHD increases with genetic distancing between donor and recipient. Recipients of HPC transplantation from identical siblings have a lower chance of developing GVHD compared with recipients of HPC transplants from HLA-matched unrelated donors and partial HLA-matched realated donors.[176,177] However, although the genetic closeness between donor and recipient appears to decrease the risk of GVHD, it also decreases the therapeutic benefit of the GVN effect and increases the chances of tumor relapse.

Graft-versus-Neoplasia Effect

It was first recognized that a beneficial collateral effect of GVHD was the rejection of neoplastic cells by the donor immune system in the context of hematologic malignancies (graft-versus-leukemia effect).[165] It was rapidly recognized that the graft-versus-leukemia effect could play a powerful therapeutic role in the treatment of refractory malignant disorders, including some solid tumors (graft-versus-tumor effect).[161] Because the biology and clinical principles underlining the two effects are likely similar, for simplicity, in this chapter we coin a unifying term: graft-versus-neoplasia effect.

It is believed that the GVN reaction is the most potent form of tumor immunotherapy currently in clinical use. However, the mechanism(s) responsible for the GVN effect are still poorly understood. T cells definitely play a fundamental role in the initiation and maintenance of the alloreaction toward neoplastic cells.[178] In fact a sevenfold increase in the chance of disease relapse was noted in patients with chronic myelogenous leukemia who received a T cell–depleted HPC transplant compared with a subset of patients who had received a T cell–replete HPC transplant but did not develop GVHD.[172,173] This result suggests that GVHD is a biologic entity different from the GVN effect. In addition, on relapse of chronic myelogenous leukemia, the administration of lymphocytes from the transplant donor can re-induce clinical remission.[179] Finally, leukemia-specific CD8+ T cells have been identified among circulating lymphocytes at the time of leukemia regression.[180] NK cells also play a role in mediating this phenomenon; clinical data suggests that mismatch of NK receptor and ligands during allogeneic BMT may be used to enhance the GVN effect.[89,181]

Appreciation of the GVN effect has led to the development of nonmyeloablative stem cell transplants designed to immune suppress the host only to a level sufficient to permit engraftment of the donor immune cells to generate the GVN effect without inducing the serious complications associated with myeloablation.[174] With nonmyeloablative HPC transplantation, GVHD and the GVN effect are being used as the primary antitumor therapy rather than high-dose chemotherapy. The use of nonmyeloablative HCP transplants and their associated GVN effect has gained popularity in the last decade to the point that this allogeneic-based immunotherapeutic approach has been advocated for several nonhematologic malignancies.[174] The rationale is largely based on the assumption that the immune cell repertoire capable of

recognizing cancer cells in the allogeneic context is broader than that in the autologous system. Donor T cells may target not only tumor-specific antigens, but also allelic variants of antigens expressed by the tumor such as mHA and, in the case of HLA-mismatched transplants, HLA antigens disparate from the donor.[182–184] Although there are several theories about how GVN effect occurs, it remains unclear why allo-T cells have a better chance of targeting tumor cells compared with the natural antitumor immunity described in patients with several type of solid tumors.

HLA and T Cell–Directed Immunization

The past decade has witnessed remarkable progress in the identification and mapping of T-cell epitopes for various infectious diseases and cancers. In particular, progress has been made in mapping HLA-associated epitopes for HIV, CMV, and EBV.[185–188] In addition, the molecular identification of tumor-associated antigens has yielded a large number of epitopes that could be used to immunize against neoplasia.[189] A comprehensive discussion of these topics is beyond the scope of this chapter, but we address a few points framing the relevance of HLA in the context of T cell–directed immunization.

The identification of T-cell epitopes led to two major areas of clinical investigation: active-specific immunization to prevent or treat ongoing infections or cancer and the harvest and in vitro expansion of immunization-induced T cells for adoptive transfer. In general, active immunization has proven successful in inducing epitope-specific T cells easily detectable among circulating lymphocytes.[113,190–192] However, in most cases, the immunization-induced enhancement of T-cell function is not associated with clinical improvement. Although the reason for the clinical ineffectiveness of immunization-induced T cells is unclear, it has been postulated that they may be quantitatively[191] or qualitatively[193] inadequate for eradicating disease. Therefore, a second strategy is being pursued, whereby the number of antigen-specific T cells is amplified in vitro for autologous or donor-derived adoptive transfer. This second strategy has met some promising success in the context of ganciclovir-resistant CMV infection,[194] EBV-induced post-transplant lymphoproliferative disorders,[195] and metastatic melanoma.[196]

Whether delivered as a primary form of therapy or to prime in vivo T cells for further ex vivo expansion, epitope-specific vaccination is limited by the stringent requirement for HLA allelic association or HLA restriction. Although superfamilies of HLA alleles may share epitopes,[18,19] in practical terms, clinically relevant HLA–epitope associations are restricted to a few peptide–allele combinations for a given protein.[23] Thus, patients considered for enrollment in immunization protocols are best served by high-resolution HLA typing to exclude subtypes with unproven immunogenic potential for a given epitope.

To overcome the stringent HLA requirements for successful epitope-specific vaccination, some protocols have used entire peptides, based on the assumption that the epitope repertoire of a protein can be adjusted to specific HLA phenotypes by a cellular process of self-selection that naturally couples peptides to HLA molecules according to their binding affinity. The peptide(s) within the protein with the greatest binding affinity are bound by the molecules. Although theoretically sound, in practice the truth of this assumption depends on the efficiency with which individual molecules are processed and presented in association with distinct HLA alleles. Even in clinical settings where this method of vaccination or sensitization is used, high-resolution typing is desirable because it allows accurate interpretation of immunization results by allowing a comparison between the detailed genetic makeup of the individual receiving the vaccine and his or her antigen-specific immune response. Thus, it is likely that in the future HLA laboratories will increasingly be required to provide high-resolution, definitive typing for enrollment of patients into vaccination protocols and for subsequent interpretation of immune responses.

Monitoring Immune Responses with Tetrameric HLA–Peptide Complexes

The growing understanding of the molecular immunology of T-cell interactions with HLA–epitope complexes in the context of infectious disease, virally induced malignancies, and spontaneous tumors and interest in their treatment with T cell–directed vaccines has sparked an interest in accurate methods to quantify ex vivo the extent of antigen-specific immune responses.[197] The most widely used assays for the enumeration of antigen-specific T cells include tetrameric HLA–peptide complexes (tHLA), intracellular flow cytometry staining for cytokines expressed on cognate peptide stimulation, detection of cytokine release by ELISPOT, and quantitative real-time PCR.[198]

Tetrameric HLA–peptide are complexes of four HLA molecules combined with a specific peptide and bound to a fluorochrome[199] (Fig. 10–8). These complexes bind to the complementary TCR and therefore identify antigen-specific T cells.[200]These tHLA can measure cellular responses against specific epitopes with sensitivity as low as 1/5000 CD8+ T cells. To synthesize tHLA molecules, soluble HLA heavy chain containing a biotinylation site and recombinant β_2-microglobulin are synthesized and purified. They are then refolded in the presence of the specific epitope and the monomer is isolated by gel filtration and biotinylated. Fluorescent streptavidin is added to induce tetramerization. An aliquot of tetramer is added to the peripheral blood mononuclear cells together with other antibodies for a more detailed characterization of antigen-specific T cells.[193] Analysis is performed using a flow cytometer. Due to the specificity of vaccines, the HLA type of the patient and the specific peptide must be identified and synthesized to provide the adequate tetramer.

Analysis of tHLA offers many potential advantages over other T-cell assays. This method is quantitative and enables an estimation of the avidity between TCR and peptide-loaded HLA class I molecules. In addition, tHLA staining does not kill the labeled cells, allowing sorting of subpopulations by flow cytometry for additional analysis or expansion for adoptive transfer. With tHLA, specific T cells can be analyzed from blood samples without the prerequisite of in vitro culture, and all specific cytotoxic T lymphocytes are detected, regardless of their functional status.[191,193]

Summary

The relevance of HLA in clinical pathology has broadened from a predictor of allosensitization to a mediator of GVHD and the GVN effect. In addition, understanding of the mechanism of action of various nonclassical HLA genes as well as KIRs has opened a new field involving the study of the innate immune response in the context of transplantation.

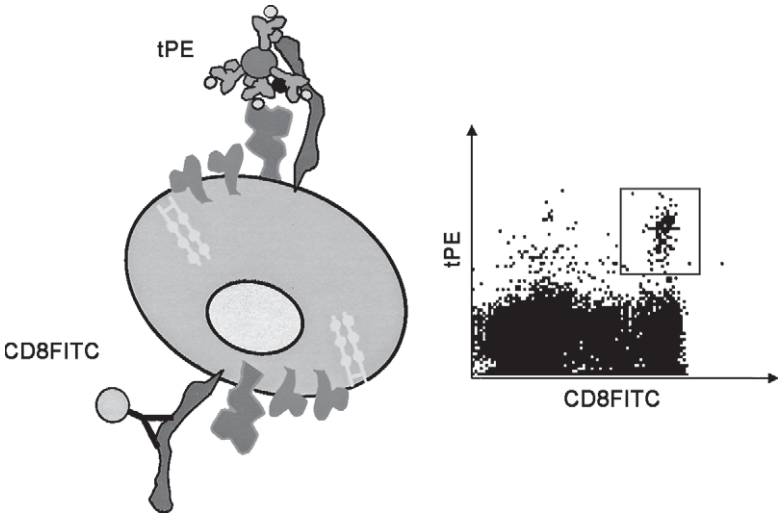

Figure 10–8 Schematic representation of the mechanism of binding of tetrameric peptide–HLA complexes (tHLA) to antigen-specific T cells. *A,* Binding of tHLA to TCR. The tHLA consists of four HLA–peptide complexes identical to the ones recognized by the T cell on the surface of live cells. Each HLA molecule is modified to contain one biotin molecule that serves as a bridge for binding to tetravalent strepavidin molecules fluorescently labeled. *B,* Actual FAC analysis result of CD8+, tHLA-positive T cells. Together with HLA, the study of immunogenetics is experiencing rapid growth that is driven by the realization that polymorphism in molecules such as mHA, KIR, cytokines, and their receptors is an important hallmark of human immune pathology. Modern histocompatibility and immunogenetics laboratories must be able to adopt high-throughput systems for the parallel assessment of all these variables when addressing the genetic makeup of an individual in correlation with the natural or therapeutic history of his or her disease. The comparison of donor and recipient protein profiling and cytokine polymorphism may offer new insights on the mechanism of rejection, GVHD, and GVN in transplant recipients. Finally, the increased utilization of T cell–directed immunization protocols is driving an increase in demand for high-resolution typing of HLA molecules to allow a more accurate interpretation of clinical and immunologic results.

HUMAN NEUTROPHIL ANTIGENS AND THEIR CLINICAL SIGNIFICANCE

Introduction

Lalezari and colleagues described the first neutrophil-specific antigens. These antigens were designated "N" for *neutrophil.* Each antigen system was described alphabetically and each allele was described numerically in order of discovery. They identified human neutrophil antigen 1a (HNA-1a) or NA1 in 1966; its allele, HNA-1b or NA2 in 1972[201,202]; and HNA-2a or NB1 in 1971.[203] Reports of several other granulocyte antigens followed.

The current neutrophil antigen nomenclature was established in 1998 by an International Society of Blood Transfusion (ISBT) Working Party[204] (Table 10–4). In this nomenclature antigen systems are referred to as human neutrophil antigens, or HNA. The antigen systems are indicated by integers, and specific antigens within each system are designated alphabetically by date of publication. Alleles of the coding genes are named according to the Guidelines for Human Gene Nomenclature. Five neutrophil antigen systems have been described: HNA-1, HNA-2, HNA-3, HNA-4, and HNA-5.

Genetics, Structure, and Function of Neutrophil Antigens

Genetics

HNA-1 antigens, which are located on the neutrophil low-affinity Fc receptor, Fc-γ receptor IIIb (FcγRIIIb), are encoded by the Fc-γ receptor gene, *FCGR3B,* which is located on chromosome 1q23.[205–208] This area of chromosome 1 contains a cluster of two families of FcγR genes, *FCGR2* and *FCGR3.* The *FCGR3* family is made up of *FCGR3A* and *FCGR3B,* which are located adjacent to each other on chromosome 1q23. *FCGR3B* is highly homologous to *FCGR3A*, which encodes FcγRIIIa (Table 10–5). The most important difference between the two genes is a C to T change at position 733nt in *FCGR3B* that

Differences among genes are in bold.

creates a stop codon. As a result *FCGR3A* has 21 more amino acids than *FCGR3B*.

The HNA-2a antigen is encoded by the gene *CD177,* which is located on chromosome 19q13.2. *CD177* belongs to the *Ly6* gene superfamily.[209–211] The coding region of *CD177* consists of 1311 bp that code for a protein of 416 and a signal peptide of 21 amino acids.[209] The predicted protein has two cysteine-rich domains, three potential N-linked glycosylation sites, and a potential ω-site for attachment of the glycosylphosphatidylinositol (GPI) anchor.[209]

The *Ly6* gene superfamily is also known as the urokinase-type plasminogen activator receptor (uPAR) or snake toxin family. This superfamily is characterized by conserved cysteine-rich domains. Typically these domains contain 70 to 100 amino acids, including 8 to 10 cysteine residues spaced at conserved distances. The *Ly6* superfamily includes two subfamilies, one encodes GPI-anchored glycoproteins and the other encodes secretory proteins without a GPI anchor. In general, the GPI-anchored *Ly6* proteins have domains with 10 cysteines and the secretory proteins have 8. The protein encoded by *CD177*, NB1 gp, is an exception in that it is GPI anchored, but it has only six cysteine residues in its cysteine-rich domains.[209] Most *Ly6* proteins have one cysteine-rich domain. Two exceptions are uPAR, which has three cysteine-rich domains and NB1 gp, which has two.[212] Members of this family tend to have little homology. At most, 20% to 30% of amino acids are conserved among members. The functions of these proteins are diverse, but not well understood.

Genes in the *Ly6* superfamily were first described in mice and are widely used as markers of murine hematopoietic stem cells and T-cell differentiation. *Ly6A/E* (stem cell antigen 1, or Sca-1) is used as a marker of murine hematopoietic precursor cells. Among the *Ly6* superfamily genes found in humans, CD59 or membrane inhibitor of reactive lysis and CD87 or uPAR are best described. *CD177* is most similar to *uPAR*; however, *CD177* and *uPAR* are only approximately 30% homologous.[209,210]

The gene encoding HNA-3a has not yet been identified. HNA-4a and HNA-5a are encoded by genes belonging to the integrin family of leukocyte cell adhesion molecules. This family is made up of three members sharing a common integrin β chain, β_2, but a different α chain. The leukocyte function-associated antigen (LFA-1) is a heterodimer made up of α_L or CD11a and β_2 or CD18 and is expressed on all leukocytes. The second member of this group, complement receptor 3 (CR3) or Mac-1, is made up of α_M or CD11b and β_2. The other member, CD11c/CD18, is made up of α_X (CD11c) and β_2. Mac-1 and CD11c/CD18 are expressed by granulocytes, monocytes, and NK cells. The HNA-4a antigen is located on CD11b and is encoded by *CD11B** 1;* HNA-5a antigen is located on CD11a and is encoded by *CD11A** 1.*[213]

Structure and Function of Neutrophil Antigens

The HNA-1a antigens are located on FcγRIIIb or CD16. This glycoprotein has 233 amino acids and is GPI-anchored.[205,208] The molecular weight of this heavily glycosylated protein ranges from 50 to 80 kD; differences in N-glycosylation account for the differences in molecular mass. FcγRIIIb has N-linked carbohydrate side chains, and the number of side chains differs between the HNA-1a and HNA-1b forms of the glycoprotein. The HNA-1a form of FcγRIIIb has 4 N-link side chains and it ranges in size from 50 to 65 kD; the HNA-1b form of FcγRIIIb has 6 N-linked side chains and is 65 to 80 kD.

FcγRIIIb is a low-affinity Fc receptor. It is the most abundant neutrophil low-affinity Fc-γ receptor. The low-affinity Fc-γ receptors link humoral immunity to cellular immune function; specifically, Fcγ receptors on effector cells recognize cytotoxic IgG molecules and immune complexes containing IgG molecules.

HNA-2a antigen is on NB1 gp, which is located on neutrophil plasma membranes and secondary granules[214,215] and is linked to the plasma membrane via a GPI anchor.[215,216] The molecular weight of NB1 gp is 58 to 64 kD and it contains N-linked carbohydrate side chains.[214,215] NB1 gp has been well characterized, but its function is not known.

HNA-3 antigens are located on a 70 to 95 kD glycoprotein that has not yet been fully characterized.[217] The function of this glycoprotein is not known. The HNA-4a and HNA-5 antigens are located on the $\alpha_M\beta_2$ or CR3 and $\alpha_L\beta_2$ or LFA-1 integrin molecules, which are important leukocyte adhesion molecules. The integrin $\alpha_M\beta_2$ also serves as a receptor for complement component C3bi.

Expression of Neutrophil Antigens

FcγRIIIb and HNA-1 antigens are expressed only on neutrophils. FcγRIIIb, HNA-1a, and HNA-1b antigens are expressed on all segmented neutrophils, about one half of neutrophilic metamyelocytes, and about 10% of neutrophilic myelocytes.[218] Soluble FcγRIIIb is found in plasma and both the HNA-1a and HNA-1b forms of the glycoprotein can be found in plasma.[219,220] Neutrophils release FcγRIIIb when they are stimulated in vitro or in vivo. Soluble FcγRIIIb levels are increased when neutrophils are stimulated or granulopoiesis is increased.[221] In healthy subjects given granulocyte colony-stimulating factor (G-CSF), FcγRIIIb expression by neutrophils is reduced and levels of soluble FcγRIIIb are increased.

HNA-2a is a neutrophil-specific antigen. It is expressed only on neutrophils, neutrophilic metamyelocytes, and myelocytes.[218,222] Although some GPI-anchored proteins, such as FcγRIIIb, are shed by stimulated neutrophils, NB1 gp is not, nor is soluble NB1 gp present in plasma.[215] HNA-2a is unique in that it is expressed on subpopulations of neutrophils. The mean size of the HNA-2a-positive subpopulation of neutrophils is 45% to 65%.[215,223,224] The expression of HNA-2a is greater on neutrophils from women than men.[224,225] The size of the HNA-2a-positive subpopulation of neutrophils from women is approximately 60% to 70% compared to approximately 50% to 60% for men. The expression of HNA-2a falls with age in women, but remains constant in men.[224] Neutrophil expression of HNA-2a is greater in pregnant women than in healthy female blood donors.[226,227]

The surface expression of HNA-2a is slightly upregulated by treatment with the chemotactic peptide f-Met-Leu-Phe.[215,216] The administration of G-CSF to healthy subjects for several days increases the proportion of neutrophils expressing HNA-2a to near 90%.[228] Patients with polycythemia vera have markedly increased levels of *CD177* mRNA, but the levels of NB1 gp expressed by neutrophils from patients with polycythemia vera have been reported to be normal.[229] However, NB1 gp expression has not been studied thoroughly in patients with polycythemia vera.

Unlike the HNA-1 and HNA-2 antigens, the other neutrophil antigens HNA-3, HNA-4, and HNA-5 are expressed by several other cell types. HNA-3a is expressed by neutrophils, lymphocytes, platelets, endothelial cells, and kidney, spleen, and placental cells.[217] HNA-4a is expressed on granulocytes, monocytes, and NK cells; HNA-5a is expressed on all leukocytes.

Neutrophil Antigen Polymorphisms and Clinical Significance

Neutrophil Antigen Polymorphisms

The neutrophil-specific HNA-1 antigen system is made up of the three alleles HNA-1a, HNA-1b, and HNA-1c[230,231] (see Table 10–4). The gene frequencies of the three alleles vary widely among different racial groups. Among whites the frequency of the gene encoding HNA-1a, *FCGR3B* 1*, is between 0.30 and 0.37 and the frequency of the gene encoding HNA-1b, *FCGR3B* 2*, is from 0.63 to 0.70.[231–236] In contrast, among Asian populations the *FCGR3B* 2* gene is more common. In Japanese and Chinese populations the *FCGR3B* 1* gene frequency ranges from 0.60 to 0.66 and the *FCGR3B* 2* gene frequency from 0.30 to 0.33.[233,235–237] The gene frequency of the gene encoding HNA-1c, *FCGR3B* 3*, also varies among racial groups. *FCGR3B* 3* is expressed by neutrophils from 4% to 5% of Caucasians and 25% to 38% of African Americans.[231]

The structures of *FCGR3B* 1*, *FCGR3B* 2*, and *FCGR3B* 3* alleles are very similar. The *FCGR3B* 1* gene differs from the *FCGR3B* 2* gene by only five nucleotides in the coding region, at positions 141, 147, 227, 277, and 349[205–208] (see Table 10-5). Four of the nucleotide changes result in changes in amino acid sequence between the HNA-1a and HNA-1b forms of the glycoprotein. The fifth polymorphism at 147 is silent. The glycosylation pattern of the protein differs between the two antigens because of two nucleotide changes at bases 227 and 277. The HNA-1b form has six N-linked glycosylation sites and the HNA-1a form has four glycosylation sites.

The gene encoding the HNA-1c form FcγRIIIb, *FCGR3B* 3*, is identical to *FCGR3B* 2* except for a C to A substitution at nucleotide 266. The nucleotide substitution results in an Alanine to Aspartate change at amino acid 78 of FcγRIIIb[230] (see Table 10–5). In many cases *FCGR3B* 3* exists on the same chromosome with a second or duplicate *FCGR3B* gene.[238] One group has found that in Danish people, *FCGR3B* 3* always exists as a duplicate gene in association with *FCGR3B* 1*.[239] However, in other populations duplicate *FCGR3B* 3* genes were associated with both *FCGR3B* 1* and *FCGR3B* 2*.

Several other sequence variations in *FCGR3B* have been described.[234,237] These chimeric alleles have single-base substitutions involving one of the five single nucleotide polymorphisms that distinguish *FCGR3B* 1* and *FCGR3B* 2*. *FCGR3B* alleles that more closely resembled *FCGR3B* 2* were found more often in African Americans than in whites or Japanese.[237]

Neutrophils from some people do not express any HNA antigens.[240–242] Blood cells from patients with paroxysmal nocturnal hemoglobinuria (PNH) lack GPI-linked glycoproteins and their granulocytes express reduced amounts of FcγRIIIb and the HNA-1 antigens. In addition, genetic deficiencies of granulocyte FcγRIIIb and HNA-1 antigens have also been reported. With inherited deficiency of FcγRIIIb, the *FCGR3B* gene is deleted along with an adjacent gene, *FCGR2C*.[242] Among whites the incidence of individuals homozygous for the *FCGR3B* gene deletion is about 0.1%.[243,244] However, among Africans and African Americans the incidence is much higher; in one study 3 of 126 Africans were found to have homozygous *FCGR3B* deletions[231] and in another 1 of 53 were found to have homozygous *FCGR3B* deletions.[237]

HNA-2a is expressed on neutrophils by approximately 97% of whites, 95% of African Americans, and 89% to 99% of Japanese.[224,225,245] HNA-2a has been reported to have an allele, *NB2*, but the product of this gene cannot be reliably identified with alloantisera and no monoclonal antibody specific for NB2 has been identified.[246] Several *CD177* polymorphisms have been described. Two different groups sequenced *CD177* independently. One group sequenced it as the gene encoding HNA-2a and called the gene *NB1*[209]; the other group sequenced it as a gene overexpressed in granulocytes from people with polycythemia rubra vera and called the gene *PRV-1*.[210] The *NB1* and *PRV-1* alleles differ at only four nucelotides.[209] Bettinotti and colleagues used Human Genomic Project databases to characterize the structure of the *PRV-1* and *NB1* genes.[211] They described the intron and exon structure of *NB1;* however, they found only one gene, *CD177,* homologous to both *PRV-1* and *NB1,* suggesting that they are alleles of the same gene. In addition, they described a pseudogene homologous to exons 4 through 9 of *CD177* and adjacent to *CD177* on 19q13.2.[211]

One of the four single nucleotide substitutions that distinguish the *NB1* and *PRV-1* alleles of *CD177* affects the size of the neutrophil population that expresses HNA-2a, but these single nucleotide polymorphisms are not responsible for the HNA-2a-negative phenotype.[247,248] Instead, the HNA-2a-negative neutrophil phenotype is due to a *CD177* transcription defect.[249] HNA-2a genes from two women with HNA-2a-negative neutrophils who produced HNA-2a-specific alloantibodies have been studied, and abnormal *CD177* mDNA sequences of variable lengths were detected in both women.[249] Their neutrophil mRNA had both exons and accessory sequences that were considered to be introns. Some

cDNA containing the entire *CD177* coding sequence was identified, but all cDNA had some accessory sequences.[249]

HNA-3a has a gene frequency of 0.66, but the molecular basis of this antigen is not known.[217] HNA-4a has a phenotype frequency of 99.1% in whites and is due to a single nucleotide substitution of G to A at position 302 of *CD11B*.[213] This substitution results in an Arg to His polymorphism at amino acid 61 of the α chain of CR3, α_M. A second polymorphism of the β_2 integrins, HNA-5a, was first described as Ond[a]. A chronically transfused male with aplastic anemia became alloimmunized to HNA-5a. HNA-5a is due to a G to C single nucleotide substitution at position 2446 of *CD11A*. This change leads to an amino acid change of Arg to Thr at amino acid 766 of the α chain of LFA-1, α_L.[213]

Clinical Significance of Neutrophil Antigens

Polymorphisms of HNA-1 have been found to have only a few clinical consequences. The deletion of the entire *FCGR3B* gene does not have major clinical consequences, and most people with FcγRIIIb deficiency are healthy. However, too few patients have been studied to identify a slight increase in susceptibility to infection or autoimmune disease due to FcγRIIIb deficiency. In a study of 21 people with FcγRIIIb deficiency, 2 people were found to have autoimmune thyroiditis and 4 had multiple episodes of bacterial infections.[242] Other smaller studies and case reports have found that despite their FcγRIIIb deficiency, all individuals, except for the one person with systemic lupus erythematosus, were healthy, had no circulating immune complexes, and showed no increased susceptibility to infections.

Despite the lack of serious illness in people with FcγRIIIb deficiencies, HNA-1 polymorphisms have some effect on neutrophil function. Neutrophils that are homozygous for HNA-1b have a lower affinity for IgG3 than granulocytes homozygous for HNA-1a.[250] Neutrophils from people who are homozygous for HNA-1b phagocytize erythrocytes sensitized with IgG1 and IgG3 anti-Rh monoclonal antibodies[251] as well as bacteria opsonized with IgG1 at a lower level than granulocytes homozygous for HNA-1a.[251,252]

Several studies suggest that *FCGR3B* polymorphisms affect the incidence and outcomes of some autoimmune and inflammatory diseases, but the results of some of these studies seem contradictory. However, because *FCGR3B* is clustered with *FCGR3A* and *FCGR2* on chromosome 1q22, it is possible that some of these findings may be due in part to linkage disequilibrium among Fc receptors. Children with chronic immune thrombocytopenia purpura are more likely to be *FCGR3B*1* homozygous than controls,[253] but Spanish patients with systemic lupus erythematosus are more likely to be *FCGR3B*2* homozygous.[254] Myasthenia gravis is more severe in *FCGR3B*1* homozygous patients,[255] but multiple sclerosis is more benign in *FCGR3B*1* homozygous patients.[256] Patients with chronic granulomatous disease who are *FCGR3B*1* homozygous are less likely to develop major gastrointestinal or genital urinary tract infectious complications compared to those with chronic granulomatous disease who are heterozygous and *FCGR3B*2* homozygous.[257]

The role of NB1gp in neutrophil function is unknown. The rare women who produce HNA-2a specific alloantibodies and who lack NB1 gp are healthy. The expression of HNA-2a is reduced on neutrophils from people with PNH and chronic myelogenous leukemia.[218] It is not known if the lack of expression of HNA-2a on neutrophils from patients with PNH or chronic myelogenous leukemia has any clinical significance.

CD177 has become an important biomarker for polycythemia vera. The diagnosis of polycythemia vera can be difficult because several other clinical conditions are associated with increased hemoglobin levels. Hemoglobin levels can be increased as a secondary response to reduced arterial oxygen levels, increased erythropoietin levels, and the presence of high-oxygen affinity hemoglobin. It is important to distinguish patients with secondary erythrocytosis from those with polycythemia vera, because if not treated, patients with polycythemia vera can suffer serious thrombotic and hemorrhagic complications.

The measurement of neutrophil *CD177* mRNA is being used along with other assays by many centers to distinguish patients with increased hemoglobin levels due to secondary erythrocytosis from those with polycythemia vera.[258,259] Quantitative real-time PCR is being used to measure neutrophil *CD177* mRNA levels, and several studies have found that neutrophil levels of *CD177* mRNA are increased in polycythemia vera patients. Overall, 91% to 100% of patients with polycythemia vera have increased *CD177* mRNA levels.[258–260] In contrast, none of the patients with secondary erythrocytosis have increased *CD177* mRNA levels.[258,259]

Neutrophil *CD177* mRNA levels are also increased in some patients with myeloproliferative disorders related to polycythemia vera.[259] Neutrophil *CD177* mRNA is overexpressed in 30% to 60% of patients with essential thrombocythemia and in approximately 60% of patients with idiopathic myelofibrosis. In patients with essential thrombocythemia the overexpression of *CD177* may affect the course of their disease. Essential thrombocythemia patients with increased neutrophil *CD177* mRNA levels have an increased incidence of thrombosis and bleeding.[261]

CD177 mRNA overexpression in myeloproliferative disorders is likely secondary to a point mutation in the Janus kinase 2 (JAK2). Approximately 75% to 95% of patients with polycythemia vera have a G to T substitution in *JAK2,* which causes a Phenylalanine to be substituted for Valine at position 617 of JAK2 (V617F).[262–265] JAK2 is involved with signaling of a number of hematopoietic growth factors, including G-CSF. The JAK2 V617F gain of function mutation and the stimulation of neutrophils by physiologic G-CSF likely leads to increased JAK2 activation, increased expression of secondary signaling molecules such as the transcription factor STAT3, and increased *CD177* mRNA transcription. Interestingly, *CD177* mRNA is also overexpressed by neutrophils from healthy subjects given G-CSF.[248]

Testing for Neutrophil Antibodies and Neutrophil Antigen Typing

Many barriers surround neutrophil antibody testing and antigen typing, including limited availability of reagents, lack of commercially available test kits, and the need to use fresh neutrophils. However, neutrophil antibodies remain clinically important, and many laboratories test for these antibodies. As a result of the reduced risk of transmitting infectious diseases via blood component transfusion, attention has focused on TRALI. TRALI is now one of the most frequent causes of transfusion-associated mortality. Neutrophil antibody testing, phenotyping, and crossmatching are an important part of evaluation of patients and donors.

Neutrophil Antibody Testing

Screening for neutrophil antibodies remains technically challenging. Antibodies to some neutrophil antigens can be detected using solid phase assays; however, the clinically important antibodies to HNA-1 antigens cannot. As a result, intact neutrophils must be used for antibody screening assays. Unfortunately, neutrophils have a short life span so fresh neutrophils must be prepared daily for testing. Neutrophils are prepared from fresh whole blood using density gradient separation. Patient sera are tested in one of several assays against panels of neutrophils prepared from several donors with known phenotypes to distinguish antibodies with different specificities. The presence of HLA antibodies with broad specificities can make the detection of neutrophil antibodies difficult because neutrophils express class I antigens. HLA-specific antibodies can be separated from neutrophil-specific antibodies by absorbing serum with platelets. Alternatively, monoclonal antibody capture assays can be used to test for antibodies specific to neutrophil membrane glycoproteins.

Granulocyte Agglutination

In this assay antibodies cause neutrophils to actively agglutinate. Cells and serum are incubated for 4 to 6 hours at 30°C. When antibodies are present, neutrophils will clump. The granulocyte agglutination assay is very reliable but less sensitive than other assays. It can detect antibodies to HNA-1, HNA-2, HNA-3, HNA-4, and HNA-5 antigens and it is the only assay that can identify antibodies specific for HNA-3a.

Granulocyte Immunofluorescence and Flow Cytometry

In the granulocyte immunofluorescence assay, antigen–antibody reactions are detected using fluorescence-conjugated secondary antibodies and a fluorescent microscope. Before incubation with sera, neutrophils are treated with 1% paraformaldehyde for 5 minutes at 20°C to 24°C to help prevent nonspecific binding of antibodies to neutrophil Fc receptors and to stabilize the cell membranes. Treated neutrophils and patient sera are then incubated for 30 minutes at 37°C. Binding of antibody to the neutrophils is detected with a fluorochrome conjugated secondary antibody. To prevent nonspecific binding of the secondary antibody to neutrophil Fc receptors, $F(ab')_2$ secondary antibodies are used. The binding of antibodies in the test serum results in a uniform staining of the outside of the neutrophils. Strong reactions are readily distinguished, but considerable training is required to distinguish weak reactions from background staining.

Testing for neutrophil antibodies with flow cytometry is technically similar to the granulocyte immunofluorescence assay except that neutrophils are evaluated with a flow cytometer rather than a fluorescent microscope. The flow cytometer can more readily compare the reactions of test sera with positive and negative control sera than the fluorescent microscope.

Mixed Passive Agglutination

The mixed passive agglutination assay uses a granulocyte antigen preparation for antibody screening. This assay allows granulocyte testing trays to be prepared in large batches and frozen until testing. Antigens are extracted from isolated neutrophils using 3% sucrose.[266] The neutrophil extract is used to coat U-bottom Terasaki plates. Sera to be tested is incubated with neutrophil extract in wells for 3 hours at 22°C. Antibody binding is detected using sheep erythrocytes coated with antihuman IgG. The antigen-coated plates can be prepared and stored for at least 1 year at −80°C. The assay has been shown to detect antibodies specific for HNA-1a, HNA-1b, HNA-2a, and HNA-3a. Although results of this assay look promising, it has yet to be compared extensively with other assays or tested in international workshops.

Monoclonal Antibody Capture Assays

The monoclonal antibody capture, or monoclonal antibody immobilization of neutrophil antigens (MAINA), assay allows the detection of antibodies to specific neutrophil membrane glycoproteins. In this assay, neutrophils are incubated with test sera, washed, incubated with a murine monoclonal antibody to a specific neutrophil glycoprotein, and washed again. The neutrophils are then dissolved in a mild detergent. The soluble glycoprotein–monoclonal antibody complex is "captured" in a well with an antibody specific to mouse IgG fixed to the well bottom. An antibody specific to human IgG conjugated to alkaline phosphatase is added followed by a substrate, and the reaction is detected with a spectrophotometer.

The MAINA assay can be used to detect antibodies to FcγRIIIb (CD16), NB1 gp (CD177), LFA-1 (CD11a), and CR3 (CD11b). This assay will detect antibodies to HNA-1, HNA-2, HNA-4, and HNA-5. The use of neutrophils from panels of donors with known HNA-1 phenotypes allows the identification of antibodies specific to HNA-1a and HNA-1b. In addition, antibodies are sometimes detected that are directed to FcγRIIIb but are not specific to HNA-1a, HNA-1b, or HNA-1c. The MAINA assay permits the recognition of antibodies to specific neutrophil glycoproteins even when antibodies to HLA antigens are present.

Strategy for Antibody Detection

Most laboratories screen serum for neutrophil antibodies by granulocyte agglutination and granulocyte immunofluorescence or flow cytometry. The serum reactive with neutrophils must also be screened in an assay that can detect HLA antibodies. If the serum is reactive with neutrophils and HLA antibodies are present, then the MAINA or a similar assay is used to determine if both HLA antibodies and antibodies to neutrophil-specific antigens are present. Because the monoclonal antibody capture assays sometimes identify antibodies that cannot be detected in other assays, some laboratories test all serum samples in MAINA assays.

Phenotyping and Genotyping of Neutrophil Antigens

Phenotyping

Traditionally, neutrophil antigen phenotyping has been performed using human alloantibodies in the granulocyte agglutination or granulocyte immunofluorescence assays. However, alloantisera are difficult to obtain. Monoclonal antibodies specific to HNA-1a, HNA-1b, and HNA-2a have been described, are commercially available, and have been used to phenotype neutrophils using flow cytometry. Phenotyping with monoclonal antibodies and flow cytometry is faster and easier than phenotyping with alloantibodies because phenotyping with monoclonal antibodies can be done with whole blood instead of isolated neutrophils.

Genotyping

Because alloantibodies are difficult to obtain and monoclonal antibodies are not available for all neutrophil antigens, genotyping assays have become important. The characterization of the genes encoding the HNA-1 antigens has allowed for the development of genotyping assays for these antigens. Genotyping of HNA-1 antigens is especially important because alloantisera to HNA-1c are rare and monoclonal antibodies specific to HNA-1c do not exist. Distinguishing single nucleotide polymorphisms is usually straightforward, but genotyping for *FCGR3B* alleles is complicated by the high degree of homology between *FCGR3B* and the gene that encodes FcγRIIIa, *FCGR3A*. As a result, most laboratories use PCR-SSP to distinguish *FCGR3B* alleles.[231,233] A unique set of primers is used to amplify each of the three alleles.

Unfortunately, HNA-2a genotyping methods are not available. Because the HNA-2a-negative phenotype is due to *CD177* mRNA splicing defects,[249] SSP have been used to determine HNA-4a[267] and HNA-5a[268] genotypes. These assays are less complex than genotyping for HNA-1 antigens because these polymorphisms are due to single nucleotide polymorphisms.

Clinical Significance of Antibodies to Neutrophil Antigens

Alloimmune Neonatal Neutropenia

During pregnancy mothers can become alloimmunized to neutrophil antigens. Maternal IgG directed to neutrophils can cross the placenta and destroy the neonate's neutrophils. Maternal alloimmunization to neutrophil antigens can occur in utero and affect the first child. Most neonates experience isolated neutropenia, but the cytopenias are self-limiting and resolve as the antibody is cleared. The alloimmunized mothers produce and carry the antibodies, but the antibodies do not react with the mother's blood cells or tissues, and they have normal neutrophil counts. Antibodies to neutrophil-specific antigens HNA-1a, HNA-1b, and HNA-2a most commonly cause neonatal alloimmune neutropenia.[269] Rarely antibodies to HNA-1c and HNA-3a cause alloimmune neonatal neutropenia. Mothers with FcγRIIIb deficiency have produced FcγRIIIb-specific antibodies that caused neonatal neutropenia.[240,241,244,245] In addition, mothers without FcγRIIIb deficiency have produced antibodies specific for a high incidence FcγRIIIb antigen that have resulted in alloimmune neonatal neutropenia.[270] Neutrophil autoantibodies can cross the placenta and cause neonatal neutropenia.[271]

Newborns with alloimmune neutropenia are usually asymptomatic. Most often the neutropenia is detected in the first week of life when the neonate becomes febrile or develops an infection and a neutrophil count is done. Typically the counts are 0.1 to 0.2 $\times$ 10^9/L. Some neonates have normal neutrophil counts the first day of life, but they become neutropenic on their second day.[269] White blood cell count, platelet count, and hemoglobin are usually normal, but eosinophilia or monocytosis may be present. If a bone marrow biopsy is performed, it often shows normal numbers of erythroid progenitors and megakarocytes with hyperplasia of myeloid progenitors.

The clinical course is quite variable. An occasional infant is asymptomatic, but most affected children have an infection. The most common infections are umbilicus infections, skin infections, abscesses, and respiratory tract infections. Less commonly infants experience otitis media, urinary tract infections, and gastroenteritis. Serious infections such as sepsis, pneumonia, and meningitis can occur. The duration of the neutropenia may be as short as a few days or as long as 28 weeks.[269] The mean duration of neutropenia is about 11 weeks.[269]

For an asymptomatic child no immediate treatment may be required. Prompt and aggressive antibiotic treatment of children with fevers or other signs of infections is indicated. Intravenous immunoglobulin (IVIG) has a limited role in the treatment of neonatal alloimmune neutropenia. Approximately half the patients treated have a transient increase in count lasting only a few days. The use of G-CSF to treat alloimmune neutropenia has also had mixed results, elevating the neutrophil count in some but not all neonates.[269]

Autoimmune Neutropenia of Childhood

Autoimmune neutropenia has been well described in children.[272–275] Typically, the onset of autoimmune neutropenia of childhood begins at age 8 months, but children between ages 1 and 36 months can be affected. Most studies found that neutrophil counts recover spontaneously by age 5 years, with a median of 13 to 20 months of neutropenia.[269,272–275]

In most cases, children presented with severe neutropenia, having neutrophil counts less than 0.5 $\times$ 10^9/L. Monocytosis has been reported to occur in up to 38% of patients. Bone marrow biopsies in infected patients usually show normal to hypercellular marrow with a decreased number of mature granulocytes. Febrile episodes and infections, including bacterial skin infections, otitis media, respiratory tract infections, and urinary tract infections, are common. Life-threatening complications are rare.

Antibodies to neutrophils can be detected in up to 98% of affected patients. If an antibody specificity is identified, the antibodies are almost always specific to epitopes located on FcγRIIIb. The antibodies are directed to HNA-1a in 10% to 46% of patients, to HNA-1b in 2% to 3% of patients, and rarely to FcγRIIIb eptitopes expressed by granulocytes from all donors.[273,274]

Autoimmune neutropenia has been treated with corticosteroids, IVIG, and G-CSF. Approximately half the patients responded to IVIG, but neutrophil counts remained elevated for only 1 week. Almost all of the patients responded to G-CSF and 75% to corticosteroids; neutrophil counts remained elevated as long as the drugs were given.

Transfusion Reactions

Prior to the widespread transfusion of leukocyte-reduced blood components, approximately 0.5% of transfusions were associated with febrile nonhemolytic transfusion reactions. These febrile reactions are due to the interaction of leukocyte antibodies in the transfusion recipient with leukocytes contained in the transfused blood components. These reactions can be prevented by the use of components that have been filtered to remove leukocytes.

A more serious type of transfusion reaction associated with leukocyte antibodies is acute noncardiac pulmonary edema, or TRALI. It has been known for more than 45 years that the transfusion of leukocyte antibodies can cause pulmonary distress.[276] Evidence for the role of neutrophils in lung injury was provided in 1977 by Craddock and colleagues, who found that activated neutrophils can cause acute lung injury and respiratory distress.[277] They found that some hemodialysis membranes activated complement,

which resulted in transient neutropenia and respiratory distress.[278] In addition, they found that activated complement caused neutrophils to aggregate and resulted in pulmonary vessel leukostasis and interstitial edema.[277,278] In 1983 Popovsky and coworkers found that the transfusion of blood components containing leukocyte antibodies was sometimes associated with acute respiratory distress, which they called TRALI.[279] TRALI is characterized by acute respiratory distress occurring within 4 to 6 hours after a transfusion, characterized by dyspnea, hypoxia, and bilateral pulmonary infiltrates on chest x-ray without cardiomegaly or pulmonary vascular congestion. The mortality associated with TRALI is approximately 5%.[279] Eighty percent of patients with TRALI have rapid resolution of pulmonary infiltrates and return of arterial blood gas values to normal within 96 hours after the initial respiratory insult. However, pulmonary infiltrates have persisted for at least 7 days after the transfusion reaction in 17% of TRALI patients.

Leukocyte antibodies have also been found to cause lung injury in animal models. The infusion of alloanti-HNA-3a in an isolated rabbit lung perfused with human neutrophils caused lung injury 3 to 6 hours after the transfusion of anti-HNA-3a.[280] In this model, lung injury was dependent on the presence of complement.

Initially, TRALI was defined as only occurring when leukocyte antibodies were present in the implicated blood component.[279] However, TRALI can occur after transfusion of blood components that do not contain leukocyte antibodies. In these cases TRALI is thought to be due to the transfusion of biologically active lipids that accumulate in blood components during storage, which primes neutrophils and potentiates the toxic effects of activated neutrophils in the transfusion recipient.[281] Other studies suggest that the activation of monocytes may cause TRALI.[282] As a result a consensus group developed a definition of TRALI that was not dependent on leukocyte antibodies in the blood component.[283] TRALI was defined as acute lung injury occurring within 6 hours of a transfusion in a patient without pre-existing acute lung injury or alternative acute lung injury risk factors.[283] Acute lung injury is the acute onset of lung injury with pulmonary artery occlusion pressure ≤ 18 mmHg or without clinical evidence of left atrial hypertension, bilateral infiltrates on chest x-ray, and hypoxemia with a ratio of $PaO_2/FIO_2 \leq 300$ mmHg or oxygen saturation of ≤ 90% on room air.[283]

Transfusion-related acute lung injury has been associated with transfusion of blood components containing both neutrophil and HLA antibodies. Antibodies specific to HNA-1a, HNA-1b, HNA-3a, and HLA class I have been reported to cause TRALI.[284] Recently HLA class II antibodies have also been implicated in TRALI.[285] Antibodies specific to HNA-3a seem to be particularly potent in causing TRALI.[286–288] Three fatal cases of TRALI following the transfusion of platelet or fresh frozen plasma components containing HNA-3a specific antibodies have recently been reported. Two of the three donors with anti-HNA-3a were regular blood donors. A review of the transfusion of 25 previous donations from one of the donors found that no transfusion reactions were reported.[287] However, a review of 36 transfusions from the other donor found 15 transfusion reactions, 8 of which were severe and included respiratory symptoms.[288]

Granulocyte Transfusions

Granulocyte transfusion recipients sometimes produce antibodies specific to HNA-1a, HNA-1b, and HNA-2a.[289,290] The transfusion of granulocytes to patients with these antibodies can result in febrile transfusion reactions and pulmonary transfusion reactions.[290] Hematopoietic progenitor cell transplant recipients who produce HNA-2a antibodies as a result of granulocyte transfusions have experienced marrow graft failure.[289]

Summary

Four neutrophil antigen systems—HNA-1, HNA-2, HNA-4, and HNA-5—have been well described and the other—HNA-3—described in part. HNA-1 antigens are located on FcγRIIIb, and antibodies to these antigens are frequently implicated in autoimmune and alloimmune neutropenia. HNA-2a is located on NB1 gp, and antibodies to HNA-2a are found in patients with alloimmune and autoimmune neutropenia. This protein is overexpressed by neutrophils in patients with polycythemia rubra vera. The significance of the overexpression of the *CD177* gene is not certain, but measurement of *CD177* levels is being used to help diagnose polycythemia rubra vera. Antibodies to HNA-3a are rare, but they appear to be more likely than other neutrophil antibodies to cause TRALI. The significance, if any, to HNA-4a and HNA-5a antibodies is not certain.

B. Blood Donation

Chapter 11

Blood Donation and Collection

Gary Zeger • Eileen Selogie • Ira A. Shulman

Blood donation is critical to all of transfusion therapy, as it provides the starting product. In the United States and many other economically developed nations, all of the blood is given by volunteer, nonremunerated donors. Donated whole blood is then made into transfusable components, which include but are not limited to packed red blood cells (RBCs), platelets, and frozen plasma or cryoprecipitate. Other lesser utilized blood components, such as granulocytes and cryoprecipitate-depleted plasma, also have important therapeutic value. Individual plasma proteins, such as factor VIII, have been manufactured using recombinant methods for years; however, there is no commercial product, single or combined, with the clinical properties of frozen plasma. Each of these components make possible an extraordinary number of traditional and state-of-the-art medical therapies, including trauma surgery, organ transplantation, and cancer chemotherapy. At the time of this writing, there are no clinically effective or available substitutes for RBCs, platelets, or plasma in the United States.

In 2001, the National Blood Donor Resource Center estimated that 8 million volunteer U.S. blood donors contributed approximately 15 million whole blood donations per year, the majority of which were manufactured into separate components, such as RBCs, fresh frozen plasma, and platelets.[1] These components allowed transfusion of 29 million blood components in the United States. Thus, in the United States, the average volunteer blood donor gives blood about 1.6 times a year. Of that total, almost 2% represent donations indicated for a specific recipient other than the donor. These are generally referred to as *directed* or *designated donations.* In addition, approximately 3% of blood donations are *autologous:* blood that is donated by an individual for his or her own use, usually for a prescheduled elective surgery.[2–4] Although it is estimated that 60% of the adult population in the United States is eligible to donate blood, at present it is believed that less than 5% of the eligible population donates within any given year.[5,6] The various reasons that some people give blood readily and others do not have been studied for several decades, but the blood donation process and applicable statistics during this time have changed little, if at all.

THE PROCESS OF BLOOD DONATION

Blood donation can be divided into five processes that are directly related to the donor: recruitment, screening, physical examination, collection, and post-donation care.

Recruitment of blood donors is a specialized task. It is often performed by telerecruiters, and the message delivered must be convincing and compelling to result in a scheduled appointment to donate blood.

Once a donor has been recruited, the screening process is carried out to make sure that the donation process will be safe for the donor and that the collected blood will be safe for the recipient. The prospective donor is initially given information about criteria for eligibility for blood donation and about the process itself. The screening process consists of a questionnaire that seeks to find medical conditions and behaviors that might make donation unsafe for the donor or recipient. Critical information is confirmed by direct verbal questioning to ensure that the answers are accurate. If no disqualifying information is uncovered during the screening process, a brief physical examination follows, which includes examination of antecubital veins, followed by measurement of body temperature, donor hematocrit or hemoglobin, and heart rate.

After the venipuncture is performed, blood is collected, labeled, and temporarily stored until it can be transferred to a manufacturing center for further processing and distribution. Specimen tubes are drawn at the time of collection for infectious disease testing; these tubes are sent for testing immediately after collection.

After the donation, donors receive oral fluids and remain under observation for a period of time so that any post-donation reactions may be treated appropriately. Post-donation instructions are given to help the donor avoid untoward side effects. The donor is instructed to call the blood center with any post-donation information, such as the development of worrisome physical symptoms or information remembered that would change the answers given during the screening process.

Donor Recruitment

Maintaining an adequate blood supply is an ongoing challenge. Attrition of blood donors due to older age and illness, implementation of new regulations resulting in deferrals, or other reasons makes it difficult for blood collection centers to keep pace with the increasing demand for blood. Thus, the recruitment of new blood donors must be ongoing and vigorous. New exclusionary criteria and serologic testing make this task increasingly difficult, as does the fact that newly recruited blood donors are nearly twice as likely to have disqualifying medical conditions as are established blood donors.[7]

It is unacceptable to provide volunteer blood donors with monetary compensation (i.e., cash or cash equivalents), so the act of blood donation in the United States is voluntary. Thus, without paying donors for their time and blood, the

formidable challenges of encouraging volunteer blood donation begin at the first step of the blood collection process: donor recruitment.

Sources of Donor Motivation

The most successful approach to recruitment of volunteer blood donors has been an appeal to community responsibility. Individuals often first learn about the need for donation during blood shortages via public service announcements and appeals for blood from newspapers, radio, and television. Other donors become aware of the importance of blood donation when transfusions are needed for family and friends (or themselves).

Appeals after disasters tend to bring out community spirit in Americans. This was particularly evident after the September 11, 2001, terrorist attack on the New York World Trade Center and the Pentagon in Washington, D.C. In both instances, blood donations vastly exceeded the local demand, due to the motivation of the entire community to contribute to their fellow Americans in need.

Donating blood for a friend or relative (directed donation) has proven to be an excellent motivator and has brought many first-time blood donors into the system. Donating for one's own use (autologous donation) has also been an effective motivator.

For whatever reason each donor is motivated to give blood, he or she must be convinced that donation is truly necessary and will be appreciated. For this reason, appeals for blood should only be made when there is a significant shortage. Once the donor has been motivated to donate, making his or her blood donation a convenient and pleasant experience is critical to retaining that donor for subsequent donations. Excellent customer service is the key to retaining blood donors.

A Note about Minority Donors

Latino Americans, particularly immigrants from Mexico, are the largest growing demographic group in the United States.[8] Adequate donor recruitment and collection among this minority group is especially important because of the high percentage of blood group O among Latinos. Because group O individuals can only receive group O RBCs, a higher percentage of group O blood is necessary in areas with large Latino populations. Specialized recruiting programs are important to attract and maintain these essential donors. Appeals in Spanish to Latino organizations and in the media are of key importance. In areas with large Latino populations, an effort should be made to provide Spanish versions of all donor materials. It is also advisable to have staff members who are conversant in Spanish or to have translators readily available.

With the exception of Chagas disease, the incidence of infectious disease markers among whole blood donors in areas with large Latino populations is similar to that of other repeat whole blood donors.[9] However, the seroprevalence of Chagas disease among whole blood donors in Los Angeles is 1 in 7200, versus 1 in 93,000 among plateletpheresis donors.[10] The significant difference in this seroprevalence is due to the fact that very few Latino individuals donate apheresis platelets in Los Angeles.

African American donors are currently the second largest minority population in the United States.[9] Recruitment and donation by African Americans is particularly important, due to many factors: they make up a large percentage of the general eligible blood donor population in certain communities; the high prevalence of blood group B in the African American population; and the higher prevalence of African Americans with specific blood types (e.g., antigen-negativity for a variety of RBC antigens to which antibodies are frequently made in highly transfused populations, such as patients with sickle cell disease) that may be used for patients who have made antibodies to these antigens.

Few publications adequately address the reasons why certain minority populations do not donate blood at the same percentages as the white population. Much research is necessary to understand the needs and wants of these important donors, so that these minority donors can be successfully recruited into the blood donor system.

Paid Donors

Aside from paid plasma donors at centers that manufacture fractionated, licensed plasma products, it is not acceptable to provide monetary compensation (cash or cash equivalents) to blood donors in the United States. In the early days of blood banking, paying for blood donors was a commonplace and accepted practice. These donors were often motivated by a lack of funds to maintain drug or alcohol habits; subsequently, paid donors had a higher incidence of transfusion-transmissible diseases, particularly hepatitis, which infected many early blood recipients. In the 1970s, growing recognition of this problem[11] led the Food and Drug Administration (FDA), in its Code of Federal Regulations (CFR), to require blood from paid donors to be labeled as such.[12] As these "paid donor"-labeled units were considered to be undesirable by clinicians and hospitals, the practice of paid whole blood donations effectively died out.

In some states, however, the shortage of single donor platelet concentrates collected by apheresis technology prompted exceptions for these donations. Until January 1, 2003,[13] a few U.S. blood collection facilities continued to pay apheresis donors. Due to the previous stigma attached to paid blood donation, these centers employed screening procedures that met or exceeded those of "all-volunteer" centers. Despite studies demonstrating that these donors had infectious disease marker frequencies similar to, or better than, those of volunteer donors, these centers were eventually forced to cease paying plateletpheresis donors.[14]

Paid donation, however, is regularly utilized for the recruitment of donors in the United States for commercial source plasma. This plasma is collected by apheresis and sent for further manufacture into various plasma-derived products. Because the pooled plasma from these donations is effectively "sterilized" during the fractionation and manufacturing process, there is less concern about the potentially increased risk for infectious disease transmission by using paid donors for "source plasma." Most countries with all-volunteer commercial plasma programs have struggled, usually unsuccessfully, to meet their population's plasma derivative needs.[15]

Health Benefits of Whole Blood Donation

The proven health benefit to blood donors is the free mini-physical examination and the infectious disease screening testing performed at the time of donation. Many donors might not have otherwise become aware of diseases such as hypertension, anemia, cardiac arrhythmia, hepatitis, or human immunodeficiency virus (HIV)

infection. This information alerts the donor to seek further appropriate medical diagnosis and treatment, and may limit the transmission of infectious disease to others. Aside from these benefits, a controversial hypothesis that depletion of iron stores through whole blood donation can improve cardiovascular status[16,17] has been proposed; more research needs to be performed prior to making any claims regarding cardiac health benefits from blood donations.

Donor Incentives

Improved screening and infectious disease testing methods used for donor blood have made widespread infectious disease transmission by transfusion, as occurred in the early days of paid blood donors, a thing of the past. All-volunteer donor programs have become the base of the blood collection establishment. Although blood donor incentives such as t-shirts, gift certificates, and paid time off are acceptable gifts, rewards that can easily be converted to cash (or cash itself) are not. The issue of donor motivation caused by incentives continues to be an area of concern to the FDA and the American Association of Blood Banks (AABB). The CFR, in its definition of paid and volunteer donors, states that "Benefits, such as time off from work, membership in blood assurance programs, and cancellation of nonreplacement fees that are not readily convertible to cash, do not constitute payment within the meaning of this paragraph." The AABB[18] and FDA[19] have provided some guidance on donor incentives (Table 11–1). There is still a concern that a potential donor might be untruthful about high-risk behaviors for infectious disease to receive a gift being offered at a blood collection site. For this reason, incentives should be provided for simply attending a blood drive and attempting to donate, rather than the gift being given based on the condition of the actual donation.

Blood Credit Programs

Blood credit programs, which in the past were more popular entities, are difficult to manage logistically and practically. The implication that a blood donor will receive a credit that can eventually be cashed in for "free" blood in the future is almost always misleading. The credits are often symbolic "credits to the blood supply" and have no direct application to the donor, monetarily or otherwise. The logistics of a true crediting program are generally prohibitive, because the time and place that the credits will be redeemed is unknown, and the involved health care providers may not be party to the program.

Patients are sometimes encouraged to have friends and relatives donate blood to "replace" any that they might use. This appears to be a reasonable recruitment strategy, as long as the patient is not made to feel stressed and anxious about finding replacement donors. It is most important for the patient to understand that he or she will never be denied blood because of inability to replace blood that has been, or might be, used. Poor communication, however, might cause the patient to put blood donation pressure on family, friends, and acquaintances who may have valid reasons for not donating, thus potentially endangering the blood supply.

Motivation by Free Testing

A serious concern throughout the blood industry following the discovery of HIV in the early 1980s (and the subsequent knowledge that HIV was transmissible through transfusions), was that high-risk individuals would donate blood to obtain a free confidential HIV test. The concern that people might now donate blood to receive free blood tests (a magnet effect) has been shown to be generally unfounded, at least for HIV p24 antigen testing.[20] Nevertheless, donor centers generally make available a list of testing sites where confidential or anonymous HIV blood testing is available, to discourage a potential high-risk individual from donating.

Factors for Success

Any donor's internal motivation will only provide a finite amount of impetus for continued participation in the blood donation process. It is the job of the entire blood collection team to make the donation process as pleasant as possible. If they are successful, a hesitant first-time donor may be converted into a regular repeat blood donor. This is a worthwhile goal: regular, repeat blood donors are more reliable and have less risk of infectious disease.

Making blood donation as convenient as possible is of prime importance. After a national disaster, blood donors have stood in long lines for hours to donate blood for anonymous victims. In such times, the truly heroic nature of the motivated blood donor is evident. Under more routine circumstances, inhospitable conditions and/or poor customer service may almost certainly discourage a blood donor from making a donation. A safe and convenient location is critical to attract and retain repeat blood donors. Parking should be easily available and free. The waiting area should be clean and pleasant. Excessive waits are to be avoided, and donors should be given an accurate wait-time whenever possible. Blood center staff should be professional, knowledgeable, and courteous. Of particular importance is making sure

Table 11–1 **Examples of Donor Incentives.**

Items Considered "Paid" Incentives	Items That May Qualify as "Nonpayment"
Cash payment or cash equivalent	Tokens or prizes of nominal value (e.g., coffee cups, t-shirts, pins)
Tickets to concerts or sporting events where market for resale exists	Employee paid time off
Music media not associated with product promotions where market for resale exists	Raffle tickets, regardless of value of prize. Prize must not be transferable or readily convertible to cash
Transferable product discounts or coupons convertible to cash	Membership in blood assurance program
Vouchers for free medical tests	Medical tests performed at the time of donation
Scholarships paid directly to students	Scholarships transferred directly to academic institution
	Gift cards and gift certificates that are nontransferable, not redeemable for cash, and bear the donor's name

From Compliance Policy Guide for FDA Staff and Industry, Chapter 2, Section 230.150. Issued May 7, 2002, revised November 22, 2005. Available at http://www.fda.gov/ora/compliance_ref/cpg/cpgbio/cpg230=150final.htm. Last modified December 12, 2005. Accessed June 3, 2006.

that a new donor understands the donation process and fully knows what to expect. Donors appreciate honesty, and unpleasant or painful surprises often provoke bad feelings.

Blood Collection Sites: Fixed and Mobile

Fixed site is a widely used term for a permanent or freestanding blood collection center. The fixed site may be located in a hospital-based donor room or in a community blood center building. The site should be clean and pleasant and must meet standards of current Good Manufacturing Practices (GMP)[21] for cleanliness, ventilation, space, and temperature. Donor confidentiality must be maintained, and there must be compliance with the Health Insurance Portability and Accountability Act of 1996. Compliance with these regulations requires a screening area that provides the donor with privacy to discuss the many personal questions on the donor-screening questionnaire. There must be adequate room in the collection area for the phlebotomists to function freely, and there must be a "canteen," or refreshment area, where the donor can be orally rehydrated and observed for post-donation reactions. Properly monitored storage areas must be available for storage of blood products and equipment.

Most autologous and directed donations are performed at fixed sites. Donations that require apheresis technology, such as plateletpheresis and granulocyte collections, are also typically performed at fixed sites, although new automated blood collection technology has allowed for the collection of multiple blood products by apheresis at mobile sites as well.

Fixed sites are generally less convenient for donors than are mobile sites, as they often require additional travel, parking, and time. For this reason, a friendly, attractive, and professional staff is important. Most regular blood donors look forward to their visits and, in a sense, become part of the blood collection "family." Intensive telephone recruitment of repeat blood donors is usually necessary for a fixed site to be successful.

Plateletpheresis donations are most often collected at fixed sites. Regular plateletpheresis donors tend to differ from whole blood donors in their levels of motivation and willingness to endure longer and more uncomfortable procedures to donate their blood platelets. These donors have their blood processed by a machine for as long as 2 hours, compared to the 7 or 8 minutes needed to complete a whole blood donation. Plateletpheresis donors are able to donate more frequently (up to 24 times per year) than are whole blood donors (regular whole blood donors may only donate every 56 days). For these reasons, positive relationships between platelet donors and blood center staff appear to play a more important role in plateletpheresis donor retention. These donors are generally recruited from the ranks of repeat whole blood donors and tend to be quite steadfast and reliable.

Mobile blood drives are the ultimate in convenience for the blood donor. The donor room is essentially transported to the donor. The mobile blood collection team generally arranges mobile blood drives with a sponsoring organization, often a business, school, hospital, public service organization, religious group, or military installation. Although it is generally easier and more cost effective to run a fixed site, the convenience of a mobile drive brings many otherwise "unavailable" blood donors into the system. Once these mobile site donors have had a positive and successful blood donation experience, it is often possible to bring them to a fixed site for further donations, with effective and continuous recruitment techniques.

An adequate area must be provided by the sponsoring organization for the mobile team to set up. An experienced, well-trained collections staff is important, because everything necessary for the blood drive must be properly set up and organized on site. Essential equipment and supplies are brought by the mobile collection team, and any omission may result in cancellation of the drive or unacceptable delays. Delays and cancellations of mobile blood drives can lead to ill will between the sponsor and the blood collection center, which may dampen the likelihood of another blood drive being sponsored by that group in the future.

An alternative to using space within a school or business for a mobile blood drive is a self-contained mobile unit, usually a specially adapted bus, typically of four- to six-bed capacity. These buses are most often used for small blood drives.

Mobile blood drives should be set up along the same basic principles as fixed sites, although a certain amount of flexibility is often in order. Donor confidentiality concerns must be adhered to as best as possible, often by use of portable modular components to maintain privacy.

Recruiting for mobile blood drives requires an entirely different approach than recruiting blood donors for a fixed site. An individual from the sponsor group is often asked to organize the blood drive, by providing a personal message of support, hosting employee rallies, and designating organizers to work with a blood center representative to produce a plan for a productive and well-run blood drive. Sponsor organizers work on a personal level to recruit donors, who sign up to donate on a particular day and time. A good sponsor organizer will also do whatever is necessary to make certain each donor arrives at the appointed time. A successful drive is often followed by a recognition ceremony for all involved.

After a first successful mobile blood drive with a sponsor, future drives are generally easier to organize and run. Setting up a first-time blood drive, however, requires a blood collection center donor recruiter with excellent interpersonal and organizational skills, because it is often not a simple process to convince a sponsor to commit to a blood drive in the workplace, because of disruptions of work due to employees' taking time away from their jobs to donate blood.

Special Donations

Autologous Donation

Autologous blood donation is blood donated for the donor's own use, usually in preparation for an upcoming elective surgery. The major impetus for autologous donation is the donor's perception of eliminating the risk of transfusion-transmitted viral disease, particularly HIV and hepatitis. Recognition of transfusion-transmitted HIV in the mid-1980s greatly increased the utilization of autologous donation, which was used less frequently before that time. Another benefit of autologous donation is minimization of exposure to allogeneic red cells and leukocyte antigens that may stimulate alloantibody formation and create future transfusion compatibility problems. Some literature also suggests that allogeneic blood transfusion can lead to modulation of the recipient's immune system.[22–27]

Because the autologous donor is also the patient who will receive the donated product, deferral criteria are less stringent than for allogeneic blood donation. For example, the autologous donor can donate every 72 hours (and typically no less than 72 hours before surgery), rather than at an interval of at least 56 days. Similarly, the minimum hemoglobin level

is lowered from 12.5 to 11 g/dL for autologous donors. When multiple autologous units are requested, it is best to begin donation a few weeks in advance of the upcoming surgery. In some cases, the donor is given supplemental iron or erythropoietin injections to maintain hemoglobin levels during the autologous donation process.[28]

Collections staff who evaluate and draw autologous blood donors must have more extensive training than those who handle only routine donations. This is in part due to the fact that autologous donors tend to be older than allogeneic donors, resulting in more age-related health problems (which may thus increase the incidence of serious adverse reactions at the time of donation). The frequency of severe donor reactions requiring hospitalization, although quite low for all donors, is significantly higher among autologous donors than allogeneic donors (1 in 17,000 versus 1 in 200,000).[29] Blood center staff must also take into consideration the disease processes that made the elective surgeries necessary in the first place. Cardiac patients, for example, may have arrhythmias or symptoms of vascular disease. Orthopedic patients often have mobility problems that would adversely affect their donation experience. Blood collection staff screeners should be especially mindful of identifying those autologous donors who are at risk for ischemic heart disease, cerebrovascular disease,[30] and seizures.

The donor history form is typically abbreviated for autologous donation, insofar as risk factors for infectious disease transmission are concerned. Acceptability criteria for autologous donation often differ from routine allogeneic donation: there is a far broader list of health problems that make a donor acceptable for autologous donation that would necessitate deferral for allogeneic or routine directed donation.

Bacterial contamination of the blood product remains a risk, even for the autologous donor. Individuals with evidence of bacterial infection should be deferred from donation until the condition is resolved. Blood collection staff screeners should question the autologous donor regarding signs or symptoms of infection (e.g., fever and antibiotic use), indwelling catheters, and open wounds. Donors who have had recent procedures that could lead to a transient bacteremia, such as recent dental work or colonoscopy, are typically deferred for at least 24 hours.

Improved screening and infectious disease testing have significantly minimized the infectious disease risks of allogeneic transfusion. However, many donors and physicians continue to request autologous donation as a transfusion option. Autologous donations require more complicated donor screening and collection procedures, associated logistical problems, and associated higher costs. The autologous unit must be specifically labeled for the designated patient, and systems must be in place in both the blood center and the hospital that will guarantee that the blood arrives at the proper place, in the right condition, and in time for surgery. Occasionally, autologous blood is not available for use, due to surgery being delayed beyond the expiration of the donated blood components or due to failure of proper communication between the collection center and the hospital staff. Positive infectious disease testing or clerical errors may also delay availability of autologous blood. At the hospital, care must be taken to transfuse autologous blood before allogeneic or directed donor blood. If an adverse effect is attributed to an allogeneic or directed unit that, arguably, would never have been transfused had the autologous unit been available for use and transfused first, medicolegal consequences may ensue.

Autologous transfusion is not risk-free, so autologous units should never be transfused simply because they are available. However, individual clinicians' thresholds for transfusion of autologous blood may be somewhat lower than for allogeneic blood transfusions.[31,32] Bacterial contamination remains a risk with autologous units, and clerical errors may cause an autologous unit with positive infectious disease markers to be transfused to an unintended recipient.[33]

Excessive wastage of unused autologous blood is often an issue, because unused units are very rarely, if ever, given to other patients (i.e., "crossed over"). These units are allowed to expire at the hospital and must be discarded. "Cross-over" has been discouraged, in part, because, as a group, autologous donors have a higher frequency of infectious disease markers than regular allogeneic donors.[34] They may also have underlying disease conditions that would make them unacceptable as donors for allogeneic blood transfusion. Another factor making autologous units less desirable for allogeneic transfusion is the lower hematocrit acceptable for autologous donation, which does not meet allogeneic criteria and may provide a substandard (less potent) red cell product.

Because modern screening and testing methodologies reduce the risk of transfusion-transmitted disease, the primary medical indications for autologous donations have been reduced; however, these donations are still often medically indicated, particularly for patients who have a rare blood type. Autologous donation is also beneficial as a means of supplementing the blood supply and does provide a degree of psychological benefit to patients who fear transfusion-transmitted disease. Autologous donation may also introduce repeat donors into the system; however, the process tends not to be cost effective, as measured by traditional cost-benefit estimations.[35] Autologous donations will likely continue to decrease in popularity, unless a frightening new transfusion-transmitted pathogen, such as HIV, is discovered in the blood supply in the future.

Infectious disease testing of autologous blood and transfusion of units with positive infectious disease markers is controversial. If the blood is collected in a hospital-based donor room for use in that hospital only, infectious disease testing is not mandated. Autologous blood drawn at a community blood center, however, must be fully tested (as for allogeneic units). Autologous units positive for infectious disease must be labeled with biohazard stickers.[36,37] The AABB Standards require that if an autologus unit is to be shipped to another facility and the unit tests positive for any marker of transfusion-transmitted disease, the shipping facility shall notify the receiving trasfusion service.[38] It is the prerogative of the hospital transfusion service whether to accept autologous blood components that are positive for infectious disease(s).

Some transfusion services agree to store and transfuse autologous units that are confirmed positive for HIV, or hepatitis B or C (HBV, HCV). Evidence presented by the College of American Pathologists (CAP) indicates that many transfusion services either do not test autologous blood for infectious disease markers or knowingly collect, store, and transfuse infectious units.[39] Although transfusion of these infected units may not present an obvious risk to the donor/patient, accidental needle-sticks and splatters do put blood handlers at risk. Accidental transfusion of an infected autologous unit to the wrong recipient is possible. Storage of infectious blood components

in hospital blood banks also presents some risk to other patients, considering that at least 1 in every 25,000 blood products is transfused to the "wrong" individual.[40] In 1992, the CAP conducted a survey of 3852 hospital transfusion services and found that 34 (0.9%) had issued one or more autologous blood products to the wrong patient during the previous year, and that 20 of these units were actually transfused.[40] An analysis of 256 licensed transfusion services by The New York State Department of Health, from 1990 through 1998, indicated that 1 in 19,000 RBC units where transfused to the wrong patient or were of incorrect ABO group or Rh type.[41] In addition, preliminary data indicate the frequency of infectious disease markers among autologous donors is significantly higher than that of allogeneic donors (Table 11–2). This data, along with the decreasing benefits of autologous transfusion due to improved infectious disease testing of allogeneic blood, make the practice of storing and transfusing infected units less attractive to hospital transfusion services.

One possible reason why many transfusion services permit storage of infectious autologous units is for fear of legal action based on the Americans with Disabilities Act, which affords to asymptomatic individuals infected with HIV a protected class status.[42–46] There is a concern that not offering autologous services to these donor/patients might be interpreted as a violation of this act.[47]

Directed Donations

A directed donation is a blood donation made specifically for use by a designated patient. Directed donations are usually made by friends and family members of the patient. These donations are typically manufactured into RBCs; however, directed plateletpheresis donations are not uncommon. Using new apheresis technology, a combination of red cells and platelets (or plasma) can be donated in one sitting.

Directed donation was initially discouraged by most blood centers, for fear that the practice would institute an inequitable two-tiered blood system in which well-connected patients would have access to a safe and adequate blood supply while less fortunate patients might have none. However, the discovery of HIV in the blood supply in the early 1980s created so much demand that today directed donations have become a routine part of blood donation.

There were two schools of thought in the early days of directed donations. One suggested that individuals, under pressure to donate by friends and family members, might not be truthful about risk factors for infectious disease. These donors would, therefore, present an increased risk of infectious disease transmission to the recipient. The other way of thinking suggested that individuals would be more careful about admitting potential risk factors when making such donations. Eventually it became evident that directed donations are likely to be as safe as most first-time blood donations, but not as safe as donations from repeat donors who have a history of safe donations.[48] Although there is no evidence that directed donations are safer than routine volunteer donations, the practice often does provide a psychological sense of well-being for the patient and may alleviate the feelings of helplessness that occur when a loved one is suffering from health care problems.

Blood from directed donors is collected and tested in accordance with the same criteria that is in place for allogeneic donations and hence can be "crossed-over" and used by other patients when not required by the original intended recipient. It is the choice of the hospital transfusion service whether to utilize the practice of "crossing over." This option, however, is important to recognize, because the blood types of the donor and/or intended recipients are often not known at the time of donation; thus, incompatible directed donations are not uncommon. These units can be transfused to other patients, improving the overall blood supply. The practice of directed donation is also a valuable means of getting donors into the system, because a sizable number of these donors go on to become repeat allogeneic donors. Rather than creating a two-tiered system, as was initially feared, directed donations tend to increase the amount of blood available for all patients.

Directed donation presents a series of logistical problems not present in allogeneic donation. A physician's order must be in place indicating the number and type (e.g., platelets, RBCs) of directed units required. The blood types of the directed donors and intended recipients are often incompatible. Additionally, directed units may not be available at the time of need, because the intended directed donor was unable to donate due to fear, time constraints, or exclusionary health conditions. Fully screened and motivated donors may be unable to donate due to inadequate venous access or technical errors. Directed donations testing positive for infectious disease are discarded. For these reasons and perhaps others, directed donations may not be available for use as expected by the patient.

Communication among donors, patients, clinicians, the blood center, and the hospital transfusion service is critical

Table 11–2 **Prevalence of Donors Confirmed Positive for Transfusion-Transmitted Disease (per 10,000 donors)**

Confirmed Infection	Autologous*	Allogeneic†
HIV	3.38	0.38
HCV	110.08	8.32
HBV	13.64	3.62

HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus.

*Systemwide collection data from American Red Cross for calendar year 2004. Personal communication from Edward P. Notari IV, M.P.H, American Red Cross, Jerome H. Holland Laboratory, ARCNET Data Center.

†Wang B, Schreiber GB, Glynn SA, et al. Retrovirus Epidemiology Donor Study: Does prevalence of transfusion-transmissible viral infection reflect corresponding incidence in United States blood donors? Transfusion 2005;45:1089–1096.

for a successful directed donation program. A system must be in place to allow the patient and attending physician to know how many directed donor units are available for transfusion, so that more donors can be recruited if necessary. Good communication and successful procedures for directed donation programs avoid last-minute misunderstandings, in circumstances in which the anticipated number of directed units is not available when needed.

Medically Indicated Directed Donations

Directed donations are not safer than allogeneic donations, but they do increase the blood supply and provide a sense of security to the recipients. Most directed donations are not clinically necessary. However, circumstances do exist that require directed donations or in which a directed donation offers medical benefit. Using the same directed donor to provide small volumes of blood at regular intervals to neonates should reduce the risk of transfusion-transmitted diseases that would presumably be present with the use of multiple donors.[49] Similarly, one can use a small group of donors for chronically transfused patients (e.g., patients with sickle cell anemia or thalassemia).[50] Patients requiring rare blood types also benefit from specific directed donations, often from a blood relative. With proper authorization, the frequency of these medically indicated donations can be increased beyond that which would be acceptable for routine donation. In these instances, the slight potential donor risk is offset by the benefit to the recipient.

HLA-Matched Platelet Donors

Some blood collection centers test their plateletpheresis donors for human leukocyte antigen (HLA) type and store the data in a computerized database to have a readily available pool of donors to treat patients who have developed anti-HLA alloantibodies and require HLA-compatible platelets. The advent of platelet crossmatching techniques and the reduced frequency of alloimmunization, possibly due to leukoreduced blood products, have made the availability of a large HLA-typed donor pool less necessary than in previous years. However, orders for HLA-matched plateletpheresis products are still made, and most blood centers still offer this option to their hospital customers.

Donors with Hemochromatosis

Therapeutic phlebotomy is an accepted modality for preventing iron overload and subsequent organ damage for patients with hereditary hemochromatosis. Some blood collection centers, in the United States and elsewhere, have used units collected from individuals with hemochromatosis for allogeneic transfusion. These donors must meet all other allogeneic criteria. Recently the FDA has sanctioned this process by allowing variances for blood centers to collect blood from these individuals, provided certain donor follow-up and other stringent criteria are met.[51]

Donor Screening

Blood donors are carefully screened to minimize the risk of adverse consequences to the donor and to the recipient of the transfused blood. The screening process is made up of two distinct steps. The first is the donor history questionnaire (DHQ), a series of questions designed to expose potential health problems that might lead to adverse effects to the donor or blood recipient. The second step is an abbreviated physical evaluation of donor blood pressure, pulse, temperature, and venous access. The donor's hematocrit or hemoglobin levels are also evaluated at this time.

Donor screening and blood collection must be conducted under specific rules found in the CFR, as well as in applicable FDA guidelines and memoranda. In addition, the AABB, the preeminent nongovernmental organization involved with transfusion medicine in the United States, issues a publication, the *Standards for Blood Banks and Transfusion Services* (*Standards*),[52] which is adhered to by the majority of American blood centers and has been adopted into law, in varying degrees, by many states. The AABB *Standards* are upgraded regularly, to keep pace with current trends in transfusion medicine and the most recent federal regulations. Websites for the AABB (www.aabb.org) and the FDA (www.fda.gov/cber) are good sources for the most up-to-date transfusion-related regulations and information. Additionally, state and local regulations regarding blood collection practices often apply. Qualifying donor requirements, as stipulated in the most recent edition of the AABB *Standards,* are listed in Table 11–3.

Donor Identification and the Deferred Donor Registry (DDR)

Proper identification, often photographic, is required to confirm the donor's identity before donation.[53] This information is important if it becomes necessary to track down and notify the donor of any positive infectious disease test results. Proper identification is also required to perform a "lookback" study, to investigate whether a donor may have transmitted an infectious disease, unknown at the time of donation, to a blood recipient. Donors are asked if they have ever donated under any other name, possibly a maiden name or nickname, which would make it difficult to confirm previous donations. Correct personal identifiers are also necessary to calculate if adequate time has passed between donations.

Computers are becoming a mainstay of donor screening and tracking, but they can only work properly if supplied with accurate information. As an added precaution, the donor's name is compared against a database of individuals, the deferred donor registry (DDR), who have been disqualified from donating in the past, usually due to a positive infectious disease marker.[54] This database can be maintained with computers or by using manual methods such as microfiche.

During the early days of the HIV epidemic in the early and mid-1980s, the DDR was instituted as a precaution against individuals falsifying information to donate blood to obtain a free HIV test. The use of the DDR is still in effect today.

The Donor History Questionnaire (DHQ)

The donor history questionnaire is an extensive series of questions, often quite personal, designed to minimize the chance of adverse consequences to the blood donor and ensure a safe and potent blood product for the recipient. Questions are typically phrased in a "yes-no" format, other than the few open-ended questions regarding health care problems. The questionnaire must comply with requirements of the CFR and *Standards.* The AABB has developed a questionnaire that fulfills these requirements, which has been adopted, to some extent, by most blood centers in the United States (Table 11–4).[55]

A blood collection staff screener is required to answer any of the donor's questions and makes sure the forms are accurate and complete. It is crucial that the DHQ be completed properly: a false

Table 11–3 **AABB Standards Requirements for Donor Qualification***

Item	Category	Criteria
1	Age	≥17 years or applicable state law
2	Whole Blood Volume Collected	Maximum of 10.5 mL/kg of donor weight, including samples; blood collection container shall be cleared for volume collected
3	Donation Interval	8 weeks after whole blood donation (Standard 5.6.7.1 applies) 16 weeks after 2-unit red cell collection 4 weeks after infrequent plasmapheresis ≥2 days after plasma-, platelet-, or leukapheresis (see exceptions in Standard 5.5)
4	Blood Pressure	≤180 mm Hg systolic ≤100 mm Hg diastolic
5	Pulse	50–100 beats per minute, without pathologic irregularities; <50 beats per minute acceptable if an otherwise healthy athlete
6	Temperature	≤37.5°C (99.5°F) if measured orally, or equivalent if measured by another method
7	Hemoglobin/ Hematocrit	≥12.5 g/dL/≥38%; blood obtained by earlobe puncture shall not be used for this determination
8	Drug Therapy	Medication evaluation: Finasteride (Proscar, Propecia), isotretinoin (Accutane)—defer 1 month after last dose Dutasteride (Avodart)—defer for 6 months after last dose Acitretin (Soriatane)—defer for 3 years after last dose Etretinate (Tegison)—defer indefinitely Bovine insulin manufactured in UK—defer indefinitely Medications that irreversibly inhibit platelet function preclude use of the donor as sole source of platelets: Defer for 36 hours after ingestion of aspirin Defer for other medications as defined by the facility's medical director
9	Medical History	
	General health	The prospective donor shall appear to be in good health and shall be free of major organ disease (e.g., heart, liver, lungs), cancer, or abnormal bleeding tendency, unless determined eligible by the medical director. The venipuncture site shall be evaluated for lesions on the skin. Family history of Creutzfeldt-Jakob disease (CJD)—defer indefinitely†
	Pregnancy	Defer if pregnant in the last 6 weeks
	Receipt of blood, component, or other human tissue	Receipt of dura mater or pituitary growth hormone of human origin—defer indefinitely Receipt of blood, components, human tissue, or plasma-derived clotting factor concentrates—defer for 12 months
	Immunizations and vaccinations	Receipt of toxoids or synthetic or killed viral, bacterial, or rickettsial vaccines if donor is symptom-free and afebrile—no deferral [anthrax, cholera, diphtheria, hepatitis A, hepatitis B, influenza, Lyme disease, paratyphoid, pertussis, plague, pneumococcal polysaccharide, polio (Salk/injection), Rocky Mountain spotted fever, tetanus, typhoid (by injection)] Receipt of live attenuated viral and bacterial vaccines—defer for 2 weeks [measles (rubeola), mumps, polio (Sabin/oral), typhoid (oral), yellow fever] Receipt of live attenuated viral and bacterial vaccines—defer 4 weeks [German measles (rubella), chickenpox (varicella zoster)] Smallpox (refer to FDA Guidance) Receipt of other vaccines, including unlicensed vaccines—defer for 12 months unless otherwise indicated by medical director‡
	Infectious diseases	Defer indefinitely: History of viral hepatitis after 11th birthday Confirmed positive test for HBsAg Repeatedly reactive test for anti-HBc on more than one occasion Present or past clinical or laboratory evidence of infection with HCV, HTLV, or HIV or as excluded by current FDA regulations and recommendations for the prevention of HIV transmission by blood and components Donated the only unit of blood or component that resulted in the apparent transmission of hepatitis, HIV, or HTLV A history of babesiosis or Chagas disease Evidence or obvious stigmata of parenteral drug use Use of a needle to administer nonprescription drugs Donors recommended for indefinite deferral for risk of vCJD, as defined in most recent FDA Guidance 12-month deferral from the time of: Mucous membrane exposure to blood

Table 11–3 **AABB Standards Requirements for Donor Qualification—Continued**

Item	Category	Criteria
		Nonsterile skin penetration with instruments or equipment contaminated with blood or body fluids other than the donor's own. Includes tattoos or permanent makeup unless applied by a state-regulated entity with sterile needles and ink that is not re-used.
		Sexual contact with an individual with a confirmed positive test for HBsAg
		Sexual contact with an individual who is symptomatic (clinical evidence or diagnosis) for any viral hepatitis
		Sexual contact with an HCV-positive individual who has had clinically apparent hepatitis within the past 12 months
		Sexual contact with an individual with HIV infection or at high risk of HIV infection[§, ‖]
		Incarceration in a correctional institution (including juvenile detention, lockup, jail, or prison) for more than 72 consecutive hours
		Completion of therapy for treatment of syphilis or gonorrhea or a reactive screening test for syphilis in the absence of a negative confirmatory test
		History of syphilis or gonorrhea
		Other: West Nile virus—defer in accordance with FDA Guidance[#]
	Malaria	Prospective donors who have had a diagnosis of malaria or who have traveled or lived in an area where malaria is endemic and have had unexplained symptoms suggestive of malaria, shall be deferred for 3 years after becoming asymptomatic.
		Individual(s) who have lived for at least 5 consecutive years in areas where malaria is considered endemic by the Malarial Branch, Centers for Disease Control and Prevention, U.S. Department of Health and Human Services, shall be deferred for 3 years after departure from that area(s).
		Individuals who have traveled to an area where malaria is endemic shall be deferred for 12 months after departing that area.[**]
10	Travel	The prospective donor's travel history shall be evaluated for potential risks.[††]

or missing entry must be corrected before the blood is released for transfusion. For additional clarity, screeners may be required to confirm certain critical questions verbally.[56] For autologous donors, who may have special health problems, it is often wise to have a well-trained registered nurse participate in the screening.

Other than the "yes" or "no" questions, the DHQ uses "capture questions" that cover a variety of broad topics. When an affirmative answer is given to a particular question, additional follow-up questions are asked by the screener to obtain additional information. For example, the question "Have you ever had any type of cancer, including leukemia?" often serves as a capture question that would elicit further information.

Additionally, to ensure that donors who self-administer a paper DHQ maintain focus, several "attention" questions are included. They serve to indicate if a donor is actually paying attention to the DHQ questions. The following is an example of one of the attention questions:

In the past 6 weeks, have you been pregnant or are you pregnant now? (Males check "I am male.")

An inappropriate answer to the question would be a male answering "yes" or "no." Each blood center must define the action of the screener when a donor inappropriately answers the attention questions. Attention questions may not be necessary when using other techniques to assure donor focus, such as an audiovisual computer-assisted self-interviewing system. In recent years, methods of computerized data entry have become more common.[57]

Several blood centers have investigated the use of an abbreviated donor history questionnaire (aDHQ) for repeat donors. The aDHQ eliminates nonrepeatable event questions; identifies recent changes in health, travel, or behavior; and retains questions about risk-associated activities that might have changed since the last donation. Data presented to the FDA Blood Products Advisory Committee on March 18, 2005, showed that a significant number of donors desire faster processing with a less complicated interview. This data demonstrated no indication that the abbreviated questionnaire increases blood safety risk.[58] At this time, the FDA has not accepted the aDHQ and has requested that the AABB Donor History Task Force develop a pre-implementation study of the aDHQ (currently in progress).

The minimum age for blood donation is typically age 17, but laws vary from state to state. Collections teams must follow local regulations and make certain proper consent is obtained. In some states, parental notification and/or consent may also be necessary.

Donor History Questionnaire and Donor Safety

For the majority of blood donors, the blood volume lost at donation is restored within 48 to 72 hours. With normal vascular elasticity, blood pressure is maintained and adverse reactions are kept at a minimum. Experienced screeners are more conservative with individuals who have a history of hypertension, diabetes, atherosclerosis, or other vascular diseases that can interfere with the normal physiologic response to acute blood loss, which might precipitate a hypotensive vasovagal reaction. Although rare, an acute drop in blood pressure could precipitate symptoms of otherwise occult coronary artery or cerebrovascular disease. The incidence of these disorders increases with age, so it is wise to be cautious with elderly donors or smaller donors with lesser blood volumes, for whom the acute loss of a pint of blood provides relatively more severe strain to the circulatory system.

Open-ended questions about a donor's general state of health, medications, previous surgeries, or current health care

Table 11–4 **AABB Full-Length Donor History Questionnaire, Version 1.1, June 2005***

	Yes	No	
Are you			
1. Feeling healthy and well today?	❒	❒	
2. Currently taking an antibiotic?	❒	❒	
3. Currently taking any other medication for an infection?	❒	❒	
Please read the Medication Deferral List.			
4. Are you now taking or have you ever taken any medications on the Medication Deferral List?	❒	❒	
5. Have you read the educational materials?	❒	❒	
In the past 48 hours			
6. Have you taken aspirin or anything that has aspirin in it?	❒	❒	
In the past 6 weeks			
7. Female donors: Have you been pregnant or are you pregnant now? (Males: check "I am male.")	❒	❒	❒ I am male
In the past 8 weeks have you			
8. Donated blood, platelets, or plasma?	❒	❒	
9. Had any vaccinations or other shots?	❒	❒

problems serve to elicit potential risk factors that require careful evaluation prior to donation. Additional questions target specific medical conditions such as cardiac, lung, liver, and blood diseases; pregnancy; and cancer. A detailed discussion of the many disease states that would affect donation is beyond the scope of this chapter; however, cardiovascular disease, cerebrovascular disease, and seizure disorders are some of the primary reasons for which deferral may be indicated. Many properly controlled medical problems, such as thyroid disease, hypertension, mild seizure disorders, diabetes, and certain heart conditions, such as mitral valve prolapse, may not interfere with blood donation. It is good policy to refer difficult cases to the blood center's medical director for a final decision as to whether it is safe for the donor to donate blood. If it is not clear whether an individual meets criteria for donation, it is generally wise to err on the side of donor safety and defer the donor.

Medications are rarely of significance from the aspect of donor safety. Although angiotensin-converting enzyme inhibitors have fostered concern about potential hypotensive episodes, medications often serve to alert the screener to health problems that otherwise may have been inadvertently left out of the donor history. Use of a coronary artery dilator, for example, would indicate a history of ischemic heart disease, which might have gone unmentioned. Experienced screeners are often impressed by the lack of information that many individuals have about their own health history. Some pre-existing disease states are not mentioned by donors when completing the DHQ, as are medications and the reasons for which the medications are being taken. This may be a matter of denial or may be symptomatic of a language problem. The latter is of increasing significance as our donor population becomes more diverse.

Donor History Questionnaire and Recipient Safety

Most significantly, the DHQ exists to protect the transfusion recipient. The driving force for much of the DHQ involves screening for transfusion-transmissible infectious diseases. The greatest danger exists for diseases in which an undetected, asymptomatic carrier state exists at the time of donation. Often there are geographic or behavioral indicators that place a donor at increased risk for transmitting these diseases. The DHQ seeks to identify these risk factors to reduce the chance of disease transmission.

Viral diseases are the most tested for transfusion-transmitted pathogens. Most notorious among these is HIV, which devastated the blood supply in the early to mid 1980s. HBV and HCV (once called *non-A, non-B hepatitis*) have also caused significant morbidity and mortality in transfusion recipients. Although sophisticated infectious disease testing methodologies have significantly reduced the rate of transfusion-transmitted viral disease, the *window period* (the time during which a recently infected donor is infectious but tests negative for infectious disease markers) contributes to a low-level risk. The introduction of sensitive nucleic acid amplification technology (NAT) has shortened the window period for HCV and HIV, when compared to previous HCV and HIV antibody or HIV p24 antigen testing. However, no matter how small the risk, it is unlikely that testing will ever detect every infected blood donor, so reliance on screening cannot diminish.

Some behaviors, which have been associated with increased risk for HIV or hepatitis infection, result in indefinite deferral. These include intravenous drug use and prostitution. Male homosexual or bisexual activity, often defined as "men having sex with other men, even once, since 1977," is also considered high-risk behavior and results in indefinite deferral from allogeneic donation. Other behaviors, such as having sexual contact with a prostitute or an intravenous drug user, require a 12-month deferral from the last contact.

The DHQ is the first line of defense against such pathogens as malaria and the agents responsible for Chagas disease and Creutzfeldt-Jakob disease (CJD), for which no practical screening tests are now available in the United States.[59,60]

Donor centers should have information to indicate areas where malaria is endemic.[61] Potential donors who have traveled to an endemic area are deferred for 12 months from the date of return. Donors with a history of malaria are deferred for 3 years if symptoms do not recur.

Transmission of variant CJD (vCJD) through blood transfusion has been a controversial topic in recent years.[62,63] There has been documented disease transmission of classic CJD through dura mater grafts, pituitary-derived human growth hormone, and ineffectively sterilized electroencephalogram electrodes. Animal studies and a few reported cases in humans suggest strongly that vCJD can be transmitted by blood transfusion. Although the risk seems to be very low, the magnitude is unknown, due to the long (e.g., 30-year) incubation period. Those stricken with vCJD by eating contaminated meat products during the 1990s became symptomatic and died in just a few years.

To deal with this difficult problem, geographical screening is now in place to exclude donors who have spent time in countries where cases of vCJD have been known to occur, including the United Kingdom (UK) and much of Europe. Potential donors are indefinitely deferred who have spent a cumulative 3 months in the United Kingdom between 1980 and 1996, the period when unsafe cattle feeding practices led to an outbreak of bovine spongiform encephalopathy, or "mad cow" disease. Ingestion of infected beef at that time is believed to responsible for a number of cases of human vCJD.[64] Also indefinitely deferred are those who spent a cumulative 6 months on European military bases or a cumulative 5 years

in certain European countries other than the UK, as are those who received a blood transfusion in the UK from 1980 to the present.[65] Recipients of pituitary-derived growth hormone are deferred as are individuals with known exposure to vCJD or CJD. Until practical mass serological screening becomes available, geographical exclusions may stay in place and thousands of otherwise eligible donors will be excluded.

Exclusionary criteria are changed and updated regularly based on new threats to the blood supply. Deferral criteria may change based on improved serologic testing, and better understanding of the disease processes involved. Criteria to avoid severe acute respiratory syndrome[66] were in effect at one time, and Gulf War veterans were deferred from blood donation from 1991 to 1993 to avoid the transmission of leishmaniasis.[67–70] Donors with a history of blood-borne parasites such as babesiosis and Chagas disease are permanently deferred.

Diseases that present with severe clinical symptoms, such as hepatitis A, tend not to require special screening, because the victims are generally too sick to donate. Standards allow prospective donors who have a history of hepatitis before age 11 to be eligible for donation, provided no other cause for deferral exists.

A number of DHQ questions deal with hematologic disease, leukemia, and previous use of clotting factors. These conditions may cause abnormalities in RBCs, platelets, or plasma proteins that may lead to substandard blood products being produced.

Exposure, or even potential exposure, to another individual's blood requires a 12-month deferral. The rationale for the 12-month deferral period is that the vast majority of transfusion-transmitted infectious diseases would manifest positive serologic markers within 1 year's time. Besides blood transfusion and accidental needle-sticks, other sources of blood exposure include human bites and acupuncture, tattoos, and piercings performed with nonsterile instruments. Nonsterile body piercing (including ears) has become increasingly problematic in recent years due to the increase in popularity of piercings and tattoos. The screener should ask if the procedure was done using sterile techniques.

Vaccinations provide another area of concern for donor screening. This is particularly true for live-attenuated viral vaccines, which could theoretically infect immunocompromised individuals. Recipients of rubella and varicella zoster vaccines are deferred for 4 weeks. A 2-week deferral is required of recipients of rubeola (measles), polio (Sabin/oral), mumps, typhoid (oral), and yellow fever vaccines. Individuals vaccinated for exposure to HBV or rabies are deferred for 12 months to avoid the remote possibility of disease transmission. The American Red Cross requires a 7-day deferral period for routine (not exposure-related) HBV vaccination; the deferral time varies among different organizations. Vaccination with nonviable agents such as toxoids and nonviable antigenic material requires no deferral. Donors who are vaccinated with experimental vaccines should be carefully evaluated and deferred for at least 12 months if there is any doubt as to the safety of the agent.[71]

The September 11, 2001, terrorist attacks on the United States and subsequent attacks of anthrax, real or hoax, through the postal system created concern about bioterrorism. The United States' vulnerability to a smallpox attack resulted in plans for mass vaccinations that have caused concern in the blood banking community. Vaccination with the vaccinia virus requires a minimum of a 21-day deferral; complicated additional criteria have been established related to vaccine-related complications and whether the scab separates spontaneously. There are also deferrals for individuals who may have come in contact with a vaccine recipient. For more information, see FDA Guidance (http://www.fda.gov/cber/gdlns/smpoxdefquar.htm#iv).

Medications taken by potential donors present a significant concern for the donor screeners. Medication deferrals fall into three major categories: those that might have adverse effects on the blood recipient, those that are taken for a medical condition that might make donation unacceptable, and those that would reduce the effectiveness of a blood product.

Some drugs are teratogenic and could cause birth defects if transfused to pregnant women. These medications include finasteride (Proscar, Propecia) and isotretinoin (Accutane), each of which requires a 1-month deferral after the last dose. Leflunomide (Arava) and dutasteride (Avodart) require 3-month and 6-month deferrals, respectively. Etretinate (Tegison) requires an indefinite deferral. Drugs that might transmit infections, such as human pituitary-derived growth hormone, which is associated with CJD, are cause for indefinite deferral. In the 1980s, prior to improved screening and purification processes, hemophiliac recipients of pooled clotting factor concentrates were at very high risk for transmitting HIV and hepatitis.

Antibiotic use may indicate an active bacterial infection. Associated subclinical bacteremia may result in a contaminated blood product, which could cause serious, even fatal, consequences to the recipient.

Medications may interfere with the quality of certain blood products. This is especially true of medications that inhibit platelet function, such as aspirin. Platelet donors must have not taken aspirin within 36 hours of donation. Other medications interfering with platelet function include clopidogrel (Plavix) and ticlopidine (Ticlid).

The CFR and AABB *Standards* provide some specific guidelines with which blood collections facilities must adhere, but it is impossible to attempt to provide specific guidance for all situations. This most often becomes an issue when evaluating donors with underlying health care problems. Not only might a particular condition require medical director consideration, but often the degree of clinical severity of that condition must also be considered.[72] For example, an active case of rheumatoid arthritis may require deferral, whereas a history of rheumatoid arthritis may not. In these instances, a collection center must develop its own procedures and criteria. Although not every circumstance can be dealt with in a comprehensive manner, some centers have developed comprehensive procedures to standardize this as best as possible.[73] It is occasionally necessary, however, particularly for autologous donations, to have a properly credentialed medical director review ambiguous situations and make informed decisions on a case-by-case basis. The medical director may also be needed to resolve issues about medications, potential risk factors, and any other circumstance where a medical doctor's decision is needed.

Donor Consent and Additional Information

It is necessary to obtain informed consent prior to donation. To help ensure that the prospective donor is properly informed, educational material about the donation process is

distributed, including information about screening, phlebotomy, and potential donation-related complications. The goal of this material is for the donor to understand the reasons for self-deferral and the importance of self-deferral when appropriate. The notification process for positive serologic tests may be explained as well as donor confidentiality issues. AABB *Standards* requires review of information about the symptoms of AIDS, and the possibility of infectious disease transmission through blood transfusion. This reading material should be in language simple enough that every donor can comprehend it.[74] When local demographics demand, it may be wise to accommodate donors with materials written in a language that they can understand; otherwise, translators may be necessary. The donor must acknowledge that these materials were read and that all questions were answered.

Donor Physical Examination and Hematocrit

A brief physical examination is performed to help ensure the donor's suitability for blood donation. The physical examination consists of evaluation of the donor's pulse, blood pressure, temperature, and weight. There is also an inspection of antecubital fossae as sites of venous access.

Generally, a donor must weigh at least 110 pounds to undergo routine donation. *Standards* allows donation of 10.5 mL of whole blood for every kilogram of donor weight, but most centers purchase blood bags with a premeasured amount of anticoagulant/preservative. These have a specified minimum and maximum amount of blood that can be collected for the anticoagulant and preservatives to function according to manufacturer's specifications. For this reason, the volume of whole blood donated is fairly constant: approximately 1 pint. Assuring that the donor is of the minimum weight is important because a smaller donor, with a smaller blood volume, will suffer greater relative stress to the circulatory system. This will increase the likelihood of an adverse reaction, possibly loss of consciousness or seizures. Underweight donors are particularly likely among younger individuals, who also have a higher incidence of adverse donation reactions than older individuals.[75,76] Although the weight is generally noted from the history, it is wise to actually weigh those donors who appear to be underweight. There is no maximum weight for blood donation, but the donor's weight should not exceed the maximum capacity of the center's collection equipment.

The donor's pulse must be regular and between 50 and 100 beats per minute. A lower pulse is sometimes acceptable in athletic donors, although a medical director's approval may be necessary. A physician should also evaluate first-time donors with an irregular pulse. Allogeneic donors should be deferred if there is any question about the potential donor's cardiovascular fitness. For autologous donors with irregular heartbeats, consultation or written permission from the patient's physician may be necessary.

The donor's blood pressure must be less than 180/100 mmHg on the day of donation. First-time donors may present with elevated blood pressure due to donation-related anxiety. Allowing them a few moments' rest may lower the blood pressure to acceptable levels. Screeners should also be wary of low blood pressure in donors of small stature, advanced age, or with vascular disease, such as diabetes or atherosclerosis. These individuals may not tolerate acute blood loss as well as a normotensive donor. Blood pressure medications are acceptable if the blood pressure is controlled and the donor otherwise meets donation criteria.

The prospective donor's temperature should be less than 99.6°F. An elevated temperature may indicate a disease process that might affect the blood recipient (i.e., bacterial contamination of the product) and may require medical attention for the donor.

The potential donor's antecubital fossae are evaluated for acceptable venous access. The skin is checked for rashes, scars, or other lesions that would make phlebotomy unacceptable. The presence of "tracks" indicative of intravenous drug abuse also leads to deferral.

Determination of hemoglobin/hematocrit level is an essential part of the donation process. Whole blood collection from an anemic donor jeopardizes the donor and provides a substandard product for the transfusion recipient. *Standards* and the CFR require that donors have a minimum hemoglobin of 12.5 g/dL or hematocrit of 38% or greater.

Venous blood or finger pricks are common methods for obtaining blood for hemoglobin/hematocrit determination. Earlobe sampling, once a commonly used method, has been proven inaccurate and is not longer acceptable according to *Standards*.[77–79] Hematocrit determinations are often done using the manual microcapillary tube method or a portable point of care technology. Some facilities use the copper sulfate method, which relies on the specific gravity of blood relative to copper sulfate, to determine whether a blood sample has an adequate hemoglobin level.

Confidential Unit Exclusion

Blood donors with unacceptable risk factors for transfusion-transmitted disease might be coerced into blood donation. This situation may arise at an institutional blood drive or with directed donations for a friend or family member. The donor may deny risk factors, such as homosexuality or drug abuse, for fear that a breach of confidentiality might allow this behavior to become widely known. The confidential unit exclusion (CUE) provides the opportunity for a donor to request, with confidentiality guaranteed, that unacceptable donated blood not be used for transfusion. This procedure is accomplished by affording the donor a CUE card containing the unit number and a means of indicating, if necessary, that the unit not be used for transfusion. The CUE is then placed in a locked box to be reviewed at a later time, at which time excluded units are earmarked for destruction. In addition, centers can provide a designated telephone number so that a donor can call back with additional information, when necessary, that would exclude a unit for transfusion. When first used, the infectious disease marker frequency of units designated for nonuse by CUE was significantly higher than other units: as many as 20% of anti-HIV positive units would have been diverted from transfusion due to the CUE.[80] Improved donor education, infectious disease testing, and screening techniques have made the CUE a less valuable tool.[81–83] Many CUEs are the result of donors misunderstanding the CUE directions and inadvertently checking the wrong box.[84,85] For this reason, after investigation, some centers will destroy an excluded unit but will continue to allow the donor to donate blood.[86]

Infectious Disease Testing

Although donor screening plays an undeniable role in maintaining a safe blood supply, infectious disease testing remains

the gold standard. As of 2005, blood is routinely screened for the following disease markers:

Hepatitis B surface antigen (HBsAg)
Hepatitis B core antibody (anti-HBc)
Hepatitis C virus antibody (anti-HCV)
HIV-1 and HIV-2 antibody (anti-HIV-1 and anti-HIV-2)
HTLV-I and HTLV-II antibody (anti-HTLV-I and anti-HTLV-II)
Nucleic acid amplification testing (NAT) for HIV-1 and HCV
NAT for West Nile virus (WNV)
Serologic test for syphilis

Although hepatitis plagued the blood supply for many years, it was not until the mid-1980s and the discovery that HIV was transmitted through blood transfusion that blood safety became a national obsession. Currently, the risk of transfusion-transmitted HIV may be as low as 1 in 2 million units.[87] Despite this, HIV is the most feared transfusion-transmitted disease.

Risk of HBV contamination may be as low as 1 in 100,000. NAT testing for HBV is still not in widespread use, although it is under consideration.[88,89] The debate, in part, consists of whether it is more cost effective to spend public funds on HBV vaccination programs or for NAT testing of the blood supply, and whether NAT testing would be more sensitive for "window period" detection of donors who have lost HBV antigenemia.[90,91]

The anti-HBc test is somewhat controversial.[92] It was once considered a surrogate marker for HIV, but improved serologic testing for HIV would seem to make anti-HBc unnecessary. The high false-positive rate for this marker further limits its usefulness. However, its proponents suggest that anti-HBc detects those donors who remain infectious of HBV who have lost HBsAg positivity.

Hepatitis C virus was once considered responsible for a transfusion-transmitted hepatitis rate of up to 10%. Current estimates of HCV transmission may be as low as 1 in 2 million units.

The test for antibodies to HTLV is also controversial.[93] Early on, HTLV-II was considered a possible etiologic agent of hairy-cell leukemia. This has been proven not to be the case, and HTLV-II is currently not associated with any disease process. HTLV-I is associated with adult T-cell leukemia/lymphoma in Japan and HTLV-associated myelopathy and tropical spastic paraparesis, chronic demyelinating diseases found in the Caribbean. The confirmatory test for HTLV is often time consuming and expensive. Many screening test results are not confirmed, however; the donated blood is destroyed and the donor is alarmed for no apparent reason.[94] Because HTLV-associated diseases are highly unusual in the United States, the necessity of HTLV as a screening test is unclear.

The most recent threat to the blood supply is West Nile virus. WNV is a mosquito-borne pathogen known to cause meningoencephalitis. Once it was recognized as a threat to the blood supply in 2003, NAT became available in fairly short order. In 2005, WNV seems to be an increasing threat, but the highly successful screening program has reduced its transmission by transfusion significantly.

Serologic testing for syphilis is another somewhat controversial test because transfusion-related transmission of this disease has been documented only recently. Some consider it to have value as an indicator of lifestyle problems that might make blood donation undesirable.

Collection

Prevenipuncture Procedures

The collection process begins with accurate identification of the blood donor. This is especially important in large centers where screening and phlebotomy are done in separate areas and by different staff. A unique identification number is placed on the collection bags, paperwork, and the pilot tubes collected for serologic testing. The phlebotomist applies mild pressure over the upper arm, usually with a blood pressure cuff or tourniquet. The increased venous pressure engorges the veins in the anticubital fossa, making them easier to detect for phlebotomy. Once a vein is selected, the skin is thoroughly disinfected, often using a two-step procedure utilizing soap and iodine solutions.[95] After the skin has been disinfected, the phlebotomist performs the venipuncture and the collection begins.

Whole Blood Collection

Whole blood is collected by means of venous pressure and gravity. Usually, the phlebotomy needle comes attached to a preconfigured bag system containing a premeasured amount of anticoagulant and preservative. A number of different anticoagulant/preservative preparations are available. The maximum liquid storage time for any RBC unit is currently 42 days. The number of bags in the collection set depends on intentions for further manufacture: whole blood, packed cells and plasma, or packed cells, plasma, and platelets. Multiple small bags can be attached if the blood is designated for pediatric transfusion. It is possible, through a sterile docking device, to add additional bags to a set. It is also possible to manually adjust the amount of anticoagulant in a collection bag for an underweight donor, but this requires significant time and expertise and is not done in most centers.

The collection bag is often placed on a trip-scale, which impedes further blood flow once the desired amount (usually 450 or 500 mL) has been drawn. The blood is agitated during collection, either manually or with an automated device, to ensure adequate mixing with the anticoagulant-preservative mixture in the bag. Many facilities choose to utilize a blood collection system that diverts the initial aliquot of donor blood into an integrally connected pouch. This diversion reduces the possibility that a skin plug or core cut with the needle during phlebotomy, possibly harboring bacteria, will contaminate the collection bag. Blood in the diversion pouch can be used for blood typing and viral marker testing without increasing blood loss associated with donation. This technique (diversion pouch) may reduce bacterial contamination rates in blood components overall by about 40%, with the highest reduction observed for common skin contaminants.[96,97]

Apheresis Platelet Collections

Plateletpheresis is a sophisticated technology by which blood is processed by an apheresis machine that uses centrifugation to remove a selected component of the blood and returns the rest to the donor. The most common use of this technology is for collection of apheresis platelets. Platelet donors are usually recruited from the ranks of whole blood donors. The minimum platelet count required to donate apheresis platelets is 150,000/μL. Apheresis platelet donors can donate more frequently than whole blood donors: AABB *Standards* limits apheresis platelet donations to no more than twice in a 7-day period and no more than 24 times per year. The apheresis procedure is more rigor-

ous than whole blood collection because the donor must remain connected to the apheresis machine for an extended period, often 1 to 2 hours. Another difficulty is the high incidence of hypocalcemic reactions, due to the calcium-binding anticoagulant used to keep blood from clotting in the machine.

Platelets collected through apheresis technology have some advantages over random donor platelets (RDPs, collected by centrifugation from individual whole blood units) because 1 apheresis platelet unit is the equivalent of 6 to 10 RDPs. This decreases the risk of transfusion-transmitted disease and allergic transfusion reactions. If an apheresis donor's platelet count (and patience) is sufficient, a double or even triple product can be collected at one sitting. Many apheresis platelet technologies provide a leukocyte-reduced product.

Granulocytapheresis

Granulocytapheresis produces a product of concentrated neutrophils using apheresis technology. Granulocytes are used to treat neutropenic patients with infections that are not responding to antibiotics. Donors are placed on an apheresis machine with granulocytapheresis capabilities. Not all machines can perform granulocytapheresis: many of the newer machines are specialized for collection of platelets or plasma. The machine must be properly programmed and the operator specially trained for granulocyte collections.

A significant challenge to granulocytapheresis therapy is collecting enough granulocytes to produce a therapeutic response. Granulocytapheresis donors are premedicated with corticosteroids and/or granulocyte-colony stimulating factor (G-CSF) before collection, to maximize granulocyte yield. These medications cause release of marginated granulocytes from the spleen and major blood vessels, markedly increasing the peripheral blood granulocyte count before donation.[98] Higher peripheral granulocyte blood counts result in larger granulocyte collections.

Regimens for premedication vary. An example dosage is 5 to 10 μg/kg administered subcutaneously, 12 hours before the collection procedure. It is recommended that one consult the manufacturer's package insert for specific dosage guidelines.[99–101] Corticosteroids are usually given as prednisone or dexamethasone. The latter is given as a dose of 8 to 12 mg, depending on the donor's weight, at intervals of 4 and 12 hours before the collection procedure. A uniform dose of 450 μg of G-CSF coupled with 8 mg of dexamethasone, both given 12 hours before collection, has been shown to be as effective as larger combined doses.[102]

Producing a granulocytapheresis product that is not heavily contaminated with RBCs has also been a challenge. The density of granulocytes is only slightly lower than that of RBCs, which makes it difficult to produce a clean separation. RBCs in the granulocyte product must be compatible with the recipient to avoid the possibility of an acute hemolytic transfusion reaction. To help remedy the problem of red cell contamination, differential sedimentation is enhanced by use of rouleaux-inducing agents. Both hetastarch and pentastarch are employed for this purpose, although hetastarch is more widely used for its higher granulocyte yields.[103] Hetastarch, however, is less rapidly cleared from the body and accumulates more readily in the extravascular space, which can lead to localized edema, headache, and fluid retention in repeat donors, often family members, who donate regularly over a period of several days. It may be wise to use reduced dosages for frequent donors to help avoid these effects. These adverse effects tend to be less of a problem for infrequent donors and with collections using pentastarch. Although traces of hetastarch may be detected in the donor for years, there has been no demonstrated clinical significance. Combined premedication with G-CSF, dexamethasone, and collection with the use of hetastarch have been reported to provide a product with a granulocyte yield of 4.1 to 10.8×10^{10} compared to 2.1 to 2.6×10^{10} using dexamethasone alone.[104]

Granulocytapheresis products should be administered at least daily to an adult patient to achieve a physiologic dose, and this must be repeated for a number days. This requirement creates serious logistical problems and is one reason why (along with the cost) granulocytapheresis is not more frequently utilized. Improved antibiotic therapy and the high incidence of adverse effects in the recipients of granulocytapheresis products, including pulmonary reactions and leukocyte alloimmunization, have further decreased the functionality of this therapy.[105,106]

Hematopoietic Progenitor Cells, Apheresis

Collection of hematopoietic progenitor cells by apheresis (HPC-A), often referred to as *peripheral blood stem cells* or *stem cells,* has become increasingly prevalent over the past decade. The main advantage of HPC-A over hematopoietic progenitor cells, marrow (HPC-M) is that adequate HPC-A can be collected to support several courses of high-dose chemotherapy. Furthermore, transplantation of autologous HPC-A results in a more rapid hematopoietic recovery compared to autologous HPC-M. HPCs are mobilized into the donor's peripheral blood from the bone marrow with the use of recombinant colony-stimulating factors, either G-CSF, granulocyte-macrophage colony-stimulating factor, or a combination of the two.

Autologous HPC-A collections may be performed following, without, or in conjunction with chemotherapy. Apheresis is performed for several days as necessary, until an adequate stem cell dose is achieved. The adequacy is determined by the CD34+ dose (the number of CD34+ cells per kilogram of recipient body weight). It is generally agreed that a minimum dose of 2.5×10^6/kg CD34+ cells is necessary for successful engraftment.[107] In most autologous collections, venous access is obtained through a dual- or triple-lumen catheter.

Collection of allogeneic HPC-A from HLA-matched relatives is primarily performed using G-CSF mobilization. Clinical trials have suggested that a dose of 2.0×10^6/kg CD34+ cells is a minimum threshold for transplantation.[108]

Collections of HPC-A can be stored unmodified or can be processed further with the intent of improving outcomes. These include purging of cancer cells utilizing monoclonal antibodies,[109] CD34+ selection techniques,[110] and ex vivo expansion[111] (i.e., culture techniques).

Plasmapheresis

Most plasma for transfusion is produced by centrifugation of a unit of whole blood, which produces a unit of platelet-rich plasma and a unit of RBCs. Plasma can also be obtained using apheresis technology. Apheresis plasma is usually collected from group AB donors, which is of particular value because it can be transfused to patients with any blood type, although several investigators have raised concerns regarding the impact of ABO nonidentical blood product transfusions on patient outcomes.[112] The advantage of apheresis plasma

technology is the ability to collect larger units, often called *jumbo plasma*. Larger units are desirable because fewer units are required per dose, which lessens the chance of infectious disease transmission and allergic reactions per recipient. For blood centers collecting blood for transfusion, plasma collections usually occur at an interval of 4 weeks or greater and must be compliant with FDA guidelines for "infrequent plasmapheresis."[113] These donors must meet whole blood criteria and are limited to an annual maximum of 12 L of plasma (14.4 L if at least 80 kg).

"Source" plasma is collected in large quantities by commercial firms for fractionation into plasma derivatives used to produce reagents and other plasma products. Source plasma is not for direct human transfusion. Because source plasma donors are often paid and tend to be aggressively recruited, specific regulatory requirements have been designed to protect the frequent plasmapheresis donor. These donors can donate a maximum of twice in a 7-day period, with at least 2 days between donations. Frequent donors require periodic physical examination by a physician and periodic determination of serum protein levels.

Multiple Apheresis Products

New apheresis technologies now make possible the collection of multiple products in a single donation when appropriate donor criteria are met. A double red cell product can be collected every 16 weeks if the donor meets the specified weight and hematocrit criteria. Some donors appreciate the convenience of donating less frequently. The collection of multiple products from a single donation helps to maintain an adequate blood supply and is often more cost efficient for the collection facility.

Adverse Donor Reactions and Injuries

The vasovagal reaction is the most common systemic donor reaction, occurring in 2% to 3% of donors.[114–117] These reactions often present as loss of consciousness due to a drop in blood pressure without a normal compensatory increase in heart rate. Vasovagal reactions are 5 to 10 times more frequent in younger donors (8% to 11%),[118] making careful observation especially important at high school and college blood drives. Other predisposing factors include first-time donor status,[119] low weight,[120] and a history of a previous donation reaction.[121,122] An anxiety-related psychosomatic component appears to be present because vasovagal reactions have occurred before donation and epidemic fainting is known to occur.

Vasovagal reactions often occur with short warning, during or immediately or after phlebotomy. Experienced phlebotomists know to look for lightheadedness, weakness, pallor, nausea, and diaphoresis. Excessive anxiety, often manifested by nervous talkativeness and hyperventilation, can precipitate a vasovagal reaction. Hyperventilation can result in respiratory alkalosis and hypocalcemia, which can help precipitate a vasovagal reaction.[123] In these instances, having the donor breathe into a paper bag may increase carbon dioxide levels, reversing the alkalosis and hypocalcemia. A calm, assuring demeanor by the phlebotomist will also do much to alleviate anxiety.

Approximately 5% of vasovagal reactions are syncopal and progress to loss of consciousness in about 0.08% to 0.34% of donors.[124] Syncopal reactions tend to occur after phlebotomy—about 60% occur at the refreshment table and 12% occur after the donor has left the collection site. This underscores the importance of closely observing donors even after the donation has been completed without incident. From 30% to 45% of the syncopal reactions include involuntary tetany or tonic-clonic convulsive movements.[125] These usually last less than 30 seconds; however, 20% may last longer, up to a minute or two. These can also progress to full-blown tonic-clonic seizures with associated urine incontinence. Prolonged hyperventilation can rarely lead to tetany without syncope as a result of hypocapnea leading to hypocalcemia. Severe vasovagal reactions may resemble shock clinically, except that the pulse is slow rather than fast. When the blood pressure becomes extremely low the donor often becomes pale and even cyanotic.

Mild vasovagal reactions are treated by elevating the donor's legs above his or her heart, helping to improve blood flow to the brain. Ammonium salts, cold neck compresses, and reassurance are often all that is necessary, and the donation can proceed. Treatment with intravenous fluids or medications is usually unnecessary if the donor does not have an underlying medical condition such as coronary artery or cerebrovascular disease. Experienced staff can help avoid a severe vasovagal reaction by recognizing and treating a reaction in the early stages.[126,127] Treatment of more severe vasovagal reactions, which may proceed to loss of consciousness and seizure activity, require that the donation be stopped and the needle be withdrawn to prevent local tissue injury from convulsive movements. The main risk associated with syncopal vasovagal reaction is trauma, particularly head trauma. Fractures and other significant injuries have been reported.[114] Some centers keep tongue protectors available, but damage to the tongue from convulsive movements is rare. The typical time for recovery from a vasovagal reaction is 5 to 30 minutes.

On occasion, a particularly severe reaction may require additional resources. Hospital-based donor rooms may have access to an emergency response team with a crash cart to deal with these situations. For remote centers without an onsite emergency response team, it may be prudent to call paramedics and have the donor transferred to a local emergency room if necessary. Maintaining a crash cart in the donor center with emergency life support equipment and medications is controversial. Centers that rarely see a severe reaction may have little or no actual experience with advanced life support procedures despite formal accreditation and may be unfamiliar with the available emergency equipment when needed. It may be better to have an emergency backup system, often calling 911, than to have an crash cart and not know how to use it.

Vasovagal reactions may recur within the next several hours and so donors who have had one should be advised to use caution when driving or operating heavy machinery. Donors with severe or multiple reactions should be discouraged from attempting to give blood again in the near future. Even donors who have had severe vasovagal reactions tend to recover spontaneously. No reports of deaths caused by blood donation-related vasovagal reaction appear in the medical literature, although there are reports of cardiac arrest in patients after venipuncture for blood sample collection.[128,129]

The sudden drop in blood pressure caused by a vasovagal reaction may evoke an ischemic event in donors with occlusive atherosclerotic vascular disease. These reactions tend to be rare, likely due to successful donor screening techniques.[114] The risk, of course, is higher for individuals with pre-existing

disease, so these donors should be accepted only if their disease is stable and even then with caution. Some degree of risk may be acceptable for autologous donation, which is commonplace for elective cardiac bypass surgery (if the patient does not have unstable angina).[30,130] Taking chances with a routine allogeneic donor is unacceptable, and if there is any real uncertainty, the donor should be deferred.

Cerebrovascular disease presents a special problem because loss of consciousness and mild seizure activity may be manifestations of both a vasovagal reaction and cerebrovascular ischemia. For a donor with a known history of cerebrovascular disease, distinguishing a donation reaction from a stroke or transient ischemic attack may be difficult. For the same reasons, it is generally a good idea to be cautious about accepting a donor with a poorly controlled seizure disorder.

Minor local tissue injury at the venipuncture site is a well-known complication of any venipuncuture. Postphlebotomy bruising is the most common adverse donor event. Two studies of outpatient phlebotomy suggest that the incidence of bruising may range from 9% to 16%.[131,132] Hematomas occur less commonly: approximately 0.3% at the time of donation and an additional 0.05% reported by the donor later. Hematomas, bruising, and soreness can usually be treated with compresses and acetaminophen. These hematomas generally resolve within 2 weeks.

Accidental arterial punctures are rare.[125] They may present as an unusually rapid phlebotomy with bright red blood and a pulsating needle. On recognition, the phlebotomy should be stopped and pressure should be applied for at least 10 minutes. The donor should be closely observed for an extended period. If there is any question about effective hemostasis, competent medical consultation should be obtained. Brachial artery pseudoaneurysm,[133,134] arteriovenous fistula,[135] and compartment syndrome[136] are possible sequelae of arterial puncture. All three complications are rare but do require surgical repair.

Nerve damage due to a hematoma or direct trauma is an unusual event. Reports suggestive of nerve damage occur in approximately 1 of every 6000 blood donors.[137,138] Symptoms may include pain and paresthesias at the venipuncture site extending into the donor's hand, fingers, or shoulder area. A hematoma is present in approximately 25% of cases. Approximately 40% recover in a few days and 70% recover completely within 30 days. The remaining 30% take as long as 9 months to recover. A few donors have a small area of persistent numbness even after 9 months. Rarely, significant permanent neurologic damage occurs.

Bactericidal skin cleansing solutions and adhesive tape can cause local allergic reactions and irritation despite extensive prerelease testing and FDA approval. For iodine-sensitive donors, alternative solutions can be used. Post-donation hemostasis can be attained with pressure dressings rather than adhesive tape.

A common adverse effect of apheresis donation is hypocalcemia, due to the calcium-binding citrate anticoagulant used to keep blood from clotting in the apheresis machine tubing. Return of citrated blood to the donor may cause lightheadedness and perioral and peripheral paresthesias. These are readily treated by ingestion of calcium-containing antacid tablets. On machines that allow more extensive operator control, the rate of citrate infusion can be lowered to help diminish these reactions.

Apheresis removes a limited amount of blood from the donor at any given time, so vasovagal reactions and other adverse effects precipitated by acute volume loss are less pronounced. The two-needle continuous flow technology draws blood from one vein at the same rate as processed blood is returned in the other. Intermittent single-needle technology removes and replaces blood in very small increments. The decreased rate of vasovagal reactions among apheresis donors may also be due to the fact that these donors tend to be older and more experienced with the donation process. As with whole blood donation, the frequency of adverse reactions is higher in first-time apheresis donors. Vasovagal reactions, for instance, range from 2.0% in first-time to 0.5% in repeat donations.

Other than mild citrate reactions, adverse events are seen with an overall frequency of 2.18% (428 of 19,611 donations from 17 centers).[139] The most common adverse events are related to the venipuncture, with a frequency of 1.30%. Palpable hematoma accounted for 88% of these events. The risk of a hematoma is higher for a plateletpheresis procedure than for a whole blood donation (0.3% for the latter; Table 11-5). This may be due to the extended time frame that the needle is in place compared with the 10 to 15 minutes for a whole blood collection.

Other adverse effects of apheresis include RBC hemolysis, air emboli, clots, and leaks. These have been reported but are extremely rare with improved apheresis technology and better-trained operators. The incidence of adverse apheresis reactions varies among institutions, which may be due to donor selection, operator training, or even record keeping. One program has reported an overall 0.81% frequency of adverse events; of 19,736 procedures, 47 (0.24%) were rated as serious.[140] Seven of these 47 donors required transfer to an emergency department.

A single unit plateletpheresis procedure will cause a drop in the donor's platelet count of approximately 30,000 to 50,000 platelets/μL, although a return to prepheresis levels will usually occur in a few days.[141,142] In some donors, frequent plateletpheresis may cause a gradual drop in platelets, such that collections must be discontinued, or possibly donations can be scheduled with longer intervals between donations.[143] The platelet count usually recovers in these donors over several months without treatment. Donors with persistent thrombocytopenia are deferred from platelet donation.

Lymphocytes, which have a density similar to platelets, are often lost during a plateletpheresis procedure. In theory, frequent plateletpheresis could remove enough lymphocytes, especially long-lived T lymphocytes, to cause immune dysfunction. At this time, however, no adverse clinical effects have been observed in healthy donors.[144]

The same adverse effects of plateletpheresis are also be seen with granulocytapheresis. In addition, the sedimenting agents used to effectively remove granulocytes and the medications used to stimulate the donors' granulocyte counts have additional side effects. Small doses of corticocosteroids have been reported to cause insomnia in up to 25% of donors.[145] Frequent granulocyte donors should be free of peptic ulcers, diabetes mellitus, hypertension, glaucoma, and other diseases exacerbated by prolonged use of corticosteroids. A combined dose of G-CSF and dexamethasone may cause side effects in as many as 72% of donors; these are commonly insomnia (30%), mild bone pain (41%), and headaches (30%). The latter two are readily relieved by analgesics.[146] Sedimentation agents, usually hetastarch, may cause fluid retention and allergic reactions.

Table 11–5 **The Incidence of Whole-Blood Donor Complications and of outside Medical Care**

Variable	Incidence: Observation/ Donor Complaints[†],%	Incidence: Observation and Postdonation Interview[‡], %	Outside Medical Care Reported to American Red Cross in 2003[§] (cases per 10,000)

Post-Donation Procedures

When the collection is complete, the tubing between the donor and the collection bag is clamped to stop the blood flow. Typically, pilot tubes for serologic testing are filled according to procedure, and the needle is removed. A pressure dressing is applied to the venipucture site to achieve hemostasis. When the bleeding is stopped, a bandage is generally applied and the donor is escorted to a refreshment area.

Blood remaining in the collection tubing is "stripped" into the collection bag to ensure adequate mixing with the anticoagulant/preservative solution. Refilled tubing is sealed into individual attached segments to be used for compatibility testing at a later time. The unit is then documented, stored, and transported to its next stop according to procedure.

The donor must remain in the canteen area under observation for approximately 15 minutes to ensure that the staff can quickly react should a reaction occur. Liquids are given to help replace those removed during the donation procedure.

The donor should receive a post-donation packet that includes information about caring for the venipuncture site, drinking liquids, and describes appropriate post-donation activity levels. A telephone number is provided to call if the donor has an adverse reaction or wishes to modify the health history information. Once stable, the donor can be released and possibly scheduled for the next donation.

Safety Concerns

Safety is always a concern when working with biohazardous materials. Safety issues have come under increasing regulatory surveillance, and there is particular concern about accidental exposure through used needles, lancets, and microhematocrit tubes.[147] Retractable needle covers to avoid accidental needle-sticks have become mandatory in some states. Safety devices are also available for filling pilot tubes. Disposable lancets and glass microhematocrit tubes can puncture skin if not handled properly. Proper disposal of used needles, lancets, and microcapillary hematocrit tubes in specialized "sharps" containers is mandatory. A properly designed and enforced Exposure Control Plan is a key element in preventing occupational blood exposures and transmission of blood-borne pathogens.

Although volunteer blood donors have a low prevalence of transfusion-transmitted disease,[148] use of disposable gloves should be encouraged, especially for staff with open wounds on exposed skin.[149] If a staff member is exposed, the employee should be counseled immediately and offered postexposure testing and prophylaxis for HIV infection.[150] Postexposure prophylaxis (PEP) should begin within 2 hours of exposure, so it may not be possible to delay treatment until infectious disease testing results on the donor are available. Although PEP for potential HIV transmission should be offered, its use is not justified for exposures that pose a negligible risk.[151,152] PEP, if taken, should be discontinued if the source is later determined to be HIV negative. Rapid testing of HIV of source donors or patients can facilitate making timely decisions regarding the use of HIV PEP.

Treatment for exposure to other transfusion-transmitted diseases is less time sensitive and can usually wait until testing of the donor in complete. If the donor is found to be HBsAg positive, a nonimmune staff member should be offered hepatitis B immune globulin within 7 days of exposure and HBV vaccine.[153] It is recommended that staff receive the HBV vaccine on initial employment, unless one is prohibited from receiving the vaccine for medical reasons or is otherwise already immune.

Table 11–6 **Example of Causes for Lookback Notification**

Item	Lookback Initiated If
HBsAg	Repeatedly reactive HBsAg confirmed positive by neutralization (or neutralization not done) is found in a subsequent donation whose prior test results were nonreactive **OR** Repeatedly reactive HBsAg, negative neutralization AND repeatedly reactive HBcore is found in a subsequent donation whose prior test results were nonreactive
HBcore	Repeatedly reactive anti-HBcore, and the test result of the second test method is reactive in a subsequent donation whose prior test results were nonreactive **OR** Repeatedly reactive anti-HBcore and repeatedly reactive HBsAg in a subsequent donation whose prior test results were nonreactive
HTLV-I/II	Repeatedly reactive anti-HTLV-I/II and the second test result is repeatedly reactive or not performed is found in a subsequent donation, whose prior test results were nonreactive or not previously tested
Anti-HIV-1,2	Repeatedly reactive anti-HIV-1,2 confirmed positive HIV-1 Western Blot **OR** HIV-2 EIA reactive found in a subsequent donation not previously tested or whose prior test results were nonreactive
HIV-1 NAT	NAT reactive AND HIV-1 Western Blot (or IFA) indeterminate positive or HIV-2 EIA reactive is found in a subsequent donation whose prior test results were nonreactive or prior donation was not tested
Anti-HCV	Repeatedly reactive anti-HCV with a supplemental test result of positive, indeterminate OR no supplemental test performed found in a subsequent donation whose prior donation was not previously tested with the currently licensed test, or whose prior test results were nonreactive
HCV NAT	NAT reactive with a supplemental test result of positive, indeterminate OR no supplemental test performed found in a subsequent donation whose prior donation was not previously tested, or whose prior test results were nonreactive
WNV	Current donation sample has a reactive WNV NAT. Relevant collections include those occurring between 120 days prior to the date of the reactive test and 120 days after the date of the reactive test. Donor reports a diagnosis of West Nile virus occurring between 14 days prior to the onset of illness and up to and including 120 days subsequent to the onset of illness or diagnosis, whichever is the later date. Donor reports unexplained febrile illness with headache or symptoms suggestive of WNV infection between June 1 and November 30, and Medical Director has determined this represents likely infection by WNV. A report is received regarding possible transmission of WNV by a blood component received within the 120 days prior to the onset of symptoms, or a WNV- fatality in a transfused recipient. Prompt quarantine and retrieval for in-date components collected from the donor of suspect donation in the period between 120 days before the suspect donation and up to and including 120 days after the suspect donation must be performed.
CJD or vCJD Risk factors	Subsequent to donation, the donor: is diagnosed with Creutzfeldt-Jakob disease indicates a family history of Creutzfeldt-Jakob disease acknowledges receipt of human pituitary-derived growth hormone (HGH) acknowledges receipt of a dura mater transplant indicates having spent a total time of 3 months or more in the United Kingdom from 1980 through 1996 indicates receipt of injectable products from cattle in BSE-endemic countries acknowledges spending a total time of 5 years or more in Europe, including time spent in the UK If a member of the U.S. military, a civilian military employee or a dependent of a member of the US military and spent a total of 6 months or more associated with a military base in any of the following countries: From 1980 through 1990 in Belgium, the Netherlands, or Germany From 1980 through 1996 in Spain, Portugal, Turkey, Italy, or Greece
AIDS-related	If a donor implicated in the investigation of transfusion-associated AIDS has a reactive test result for anti-HIV-1, 2 and/or HIV-1 antigen. If information is received that a patient with AIDS has previously donated blood.
High-risk behavior (e.g., travel, vaccination malaria, tattoo, blood exposure)	Post-donation information becomes available regarding a donor who would have been deferred had the information been known at the time of donation.

Compliance Issues

The management of unexpected events may often be referred to as *error* or *deviation management*. Because humans are fallible, limiting the incidence of errors to absolute zero can never be achieved.[154, 155] Well-prepared organizations approach error management from a systems level, anticipating that errors and deviations will occur, and prepare system defenses for dealing with their inevitable occurrence rather than focusing on blaming individuals for forgetfulness or inattention.[154]

Lookbacks

Being human, blood donors themselves represent a source of deviation. With the incubation time between exposure and onset of disease, some individuals are unaware that they may be infectious to others. To identify these individuals, a donor center must develop procedures to notify the recipients of blood or components of previous donations when a donor becomes confirmed positive for an infectious disease marker, or when a statement of high-risk information dis closed at a subsequent time determines that the donor was actually ineligible at the time of their donation. Identification of persons who may have received blood or components from such donors is referred to as *lookback*. Examples of causes for lookback may be seen in Table 11–6.

On identification of a unit meeting lookback criteria, a facility must search records for prior donations by the same individual. A sample worksheet may be seen in Figure 11–1. The highest priority should be placed on the most recently donated units. This should be done within 72 hours, so that any unit(s) remaining in inventory may be immediately quarantined. Policies must include consignee notification, so that any components shipped to other facilities may be immediately quarantined and returned. A sample notification letter and product disposition record may be seen in Figures 11–2 and 11–3.

If the implicated donor has donated on many occasions, lookback notification should be started with the most recent recipients. Reasonable and timely attempts must be made to notify transfusion recipients, particularly if a lookback is due to HIV[156] or HCV,[157] so that recipients may obtain testing, counseling, and medical referral as needed.

Recalls and Market Withdrawals

Errors can also result from improper testing, incorrect labeling of components, improperly interpreting test results, improperly using equipment, or failure to follow the manufacturers' directions or facility procedures. These kinds of errors may result in recalls or market withdrawals.

Recalls are defined as actions taken by a facility to remove a product from the market.[158,159] Recalls may be conducted

Date: December 1, 2005

John Doe, MD
Director, Blood Bank
General Hospital
Anywhere, CA 90000

This confirms our telephone notification that your hospital received a blood component from a donor that was subsequently found to be confirmed positive for HIV-1. All test results from prior donations were nonreactive, including those for the blood component shipped to your facility.

On November 30, 2005, at 11:25am, we telephoned your facility and spoke to Jane Doe and conveyed the following information:

UNIT NUMBER	Z987654321
TYPE OF COMPONENT	Whole Blood
ABO/RH:	O negative
EXPIRATION DATE:	12/6/2005
SHIPMENT DATE	11/25/2005

Your transfusion service reported the unit to be **transfused.**

Please complete and return the enclosed *Lookback Product Disposition Record*. Maintain a copy of the record for your files.

If you have any questions concerning this matter, please contact the Somewhere Donor Center at (555) 123-4567 x891.

Sincerely,

Name & credentials
Authorized Somewhere Donor Center contact

on a facility's own initiative, by FDA request, or by FDA order under statutory authority. FDA guidelines categorize all recalls into one of three classes according to the level of hazard involved.

A Class I recall is a situation in which there is a reasonable probability that the use of or exposure to a violative product will cause serious adverse health consequences or death. An example of products in this category would be a unit issued that was found to be HIV positive.

A Class II recall is a situation in which use of or exposure to a violative product may cause temporary or medically reversible adverse health consequences or where the probability of serious adverse health consequences is remote. An example of products in this category would be a unit later found to be collected from a donor whose hemoglobin did not meet the minimum criteria.

A Class III recall is a situation in which use of or exposure to a violative product is not likely to cause adverse health consequences. Examples of products in this category might be those that do not meet FDA labeling regulations.

Figure 11–3 Sample lookback product disposition record.

A market withdrawal occurs when a product has a minor violation that would not be subject to FDA legal action. The firm removes the product from the market or corrects the violation. For example, a product removed from the market due to tampering, without evidence of manufacturing or distribution problems, would be a market withdrawal.

Biological Product Deviation Reporting

On November 7, 2000, the FDA published a final rule[160] to amend the requirements of reporting errors and accidents in manufacturing of products. This rule was issued as part of a program to improve the effectiveness of the FDA's regulatory program. FDA replaced the term *error and accident* with the term *biological product deviation* (BPD).

Licensed blood establishments, unlicensed blood establishments, registered blood establishments, and transfusion services are required to report to the FDA all BPDs. BPDs are defined as any event associated with manufacturing of blood or blood components that EITHER:

1. Represent a deviation from current GMPs, applicable regulations, or established specifications that may

affect the safety, purity, or potency of that product OR

2. Represent an unexpected or unforeseeable event that may affect the safety, purity, or potency of that product AND
   - Occurs in your facility or a facility under contract to you AND
   - Involves a distributed blood or blood component.

Post-donation information is considered reportable to the FDA as a BPD if the donor should have been deferred had the information been known at the time of donation and the safety, purity, or potency of the product could be affected. Post-donation information also includes information that a blood center obtains when it adds new donor history questions.

In many cases blood establishments cannot control post-donation information. For example, a donor may call after donating to report a post-donation illness, or information obtained post-donation about exposure to a disease or a sex partner at high risk. Reports of post-donation information continue to represent the largest percentage of BPDs submitted by blood and plasma establishments (71%). In 88% of the reports the donor was aware of the information at the time they were interviewed, but failed to provide the information during the interview. Most often (91%), the donor center staff is made aware during a subsequent donation interview.[161]

CONCLUSION

The products of blood donation—RBCs, platelets, and plasma—are a vital resource making possible modern medicine. At this time, there are no comparable substitutes. A debt of gratitude is owed to those blood donors who give their blood, for no monetary compensation, to anonymously help save the lives of others.

At one time, all that was needed to collect blood was a collection set and a donor with suitable veins. Since then, thousands of transfusion medicine professionals have transformed the early donor rooms to a multibillion dollar industry collecting tens of millions of blood products per year. Their ceaseless efforts to improve transfusion safety have had remarkable success on the well-being of the blood recipient, donor, and even the collections staff. Unremitting efforts to improve donor screening and serologic testing for infectious disease are needed to keep ahead of potential threats to the blood supply.

For these reasons, change occurs very rapidly in the world of blood banking, and all decision-making processes require checking for the latest information available, which can be obtained through the AABB or FDA websites.

Chapter 12

Blood Manufacturing: Component Preparation, Storage, and Transportation

Shealynn B. Harris • Christopher D. Hillyer

Modern transfusion medicine in highly developed nations is based on the use of components, including cellular and plasma components, prepared or manufactured from whole blood collected from a volunteer donor. This is often called *component therapy* and offers both therapeutic and economic advantages, including the provision of concentrated products for specific and targeted transfusion management and the cost-effective and efficient use of this valuable and often limited resource. Along with the benefits of component therapy, however, there are also challenges posed by the complex manufacturing process required for component production.

In this chapter, the essentials of the blood manufacturing process will be discussed, with an emphasis placed on blood collection, component preparation, labeling, and storage. Although they are mentioned in this chapter, the areas of regulation, donor eligibility, quality control, infectious disease testing, and clinical use of components are addressed in greater detail in dedicated chapters elsewhere in this textbook.

BLOOD COLLECTION

Donor Preparation and Care

Essentially, the manufacturing of components can be thought of as beginning with the collection of blood from an eligible volunteer donor by whole blood phlebotomy or automated apheresis. Indeed, the process of blood collection is regulated under the CFR and is subject to AABB Standards. Accordingly, establishments that collect blood for transfusion or "for further manufacture" need to have adequate and appropriate standard operating procedures (SOPs), training, and equipment validation for donor collection. An effective donor selection, preparation, and collection process serves several purposes: it ensures the quality of the final products and components; it minimizes risks to both the donor and transfusion recipient; and it enhances donor satisfaction, which increases the likelihood of repeat donations.

Prior to collection, all allogeneic blood donors must be accurately identified, provide informed consent, and be evaluated for general suitability requirements, which include criteria for age, weight, donation interval, medical and pregnancy history, infectious diseases and related risk behavior, hemoglobin level, temperature, pulse, and blood pressure. If a donor is accepted for collection, the donor's identity must be effectively linked to all resulting components and test samples by a unique alphanumeric identifier.

Skin Antisepsis

Bacterial contamination of blood products is a leading cause of transfusion-related morbidity and mortality.[1] Because the donor is most often the source of bacterial contamination, either through bacteremia or skin flora, methods to reduce the risk of contamination begin with proper donor screening, arm inspection, and skin antisepsis.[2] For all types of collection procedures, donor preparation starts with the inspection of both arms for signs of intravenous drug use or skin lesions that pose an infectious disease risk.[3] This is followed by the appropriate application of one of the FDA approved skin disinfection methods for blood collection.[4] Most methods specify use of an iodine disinfectant, either povidone iodine or tincture of iodine. Because iodine can result in skin reactions in sensitive individuals, the FDA-approved 2% chlorhexidine gluconate in 70% isopropyl alcohol method is recommended by the AABB for iodine-allergic donors.[5] The use of green soap and 70% isopropyl alcohol for iodine-allergic donors is no longer recommended by the AABB, based on data that show significantly more residual skin flora after cleaning as compared to the other currently approved skin antisepsis methods listed previously.[6]

Donor Care and Complications

Care of the donor is essential to a safe and effective donation process. Because the collection staff serve as the primary interface between donors and the blood community, it is imperative that staff act in a courteous, professional manner to help promote donor satisfaction and repeat donations. In addition, to ensure donor safety, collection staff must also be aware of potential donor reactions and must be trained in collection facility procedures for reaction management.

Venipuncture, intravascular volume shifts, and apheresis-specific citrate use present risks for donation complications.[7,8] For apheresis donation, the overall frequency of complications is approximately 2%, with the majority related to mild hypocalcemia from the citrate anticoagulant.[9] In contrast, for whole blood donation, the overall frequency of complications is at least 10 times greater (20% to 40%), with bruising, arm discomfort, fatigue, vasovagal events, and nerve irritation, listed in order of decreasing frequency, as the complications most often reported.[7]

In general, for the common complications just listed, donors typically do not require significant medical intervention and readily recover without lasting sequelae. However, for donors with phlebotomy-related cutaneous nerve irritation or injury (incidence, 0.02%–0.9%), a study by Newman and Waxman[10] showed that approximately 30% will experience symptoms, typically mild numbness, lasting 1 month or

longer, and the majority of these donors will request a physician consultation. In the same study, approximately 25% of nerve injury cases were associated with a hematoma, indicating improper phlebotomy technique as a contributing factor. However, in another report by Newman,[11] approximately 40% of nerve injuries occurred after an uncomplicated phlebotomy, which suggests that phlebotomy-related nerve injury may not be completely preventable. Furthermore, an anatomical study by Horowitz[12] of the cutaneous nerve-superficial vein relationships at common venipuncture sites suggests that cutaneous nerves often overlie superficial veins, which increases the likelihood for mild nerve injury, even with proper phlebotomy technique.

Rarely, phlebotomy-related nerve injury is more severe, resulting in a chronic, disabling neuropathic pain syndrome, Complex Regional Pain Syndrome Type 2 (CRPS-II), which is characterized by shooting, burning, or electrical pain often associated with motor dysfunction.[13] In contrast to donors with mild nerve injury, 80% of donors with CRPS-II report traumatic phlebotomy with multiple attempts or hematoma formation.[13]

Although the vast majority of donor complications do not require emergency intervention or hospitalization, very serious events, defined by the need for hospitalization, do occur and are more likely with apheresis donation (1 in 20,000)[14] than with whole blood donation (1 in 200,000).[15] Because serious adverse events can take place during or immediately after donation, a plan for managing these events must be in place at the collection facility. Collection staff should be familiar with signs and symptoms of donation complications and should closely monitor donors throughout the donation process.[16]

As complications can occur or be noted after the donor leaves the collection facility, donors should be provided with postphlebotomy information,[17] which includes care of the venipuncture site, limits on strenuous physical activity, discussion of the need for increased fluid consumption, and contact instructions in the event of an adverse reaction.

Donor Test Samples

Current standards require that donors be tested for multiple infectious disease markers, ABO and Rh type, and if previously transfused or pregnant, red cell alloantibodies.[18] These testing requirements necessitate the collection of several vacuum tubes of blood from the donor. To eliminate the need for a second donor venipuncture, most collection and storage kits include a convenient method for donor sampling, either a diversion pouch or an in-line sampling system. Once test samples are obtained, the tubes must be properly labeled with the donor identifier to ensure effective traceability and proper result reporting.

Collection and Storage Kits

In addition to donor-derived bacteria, environmental pathogens, such as *Serratia marcecsens*, encountered during blood manufacturing and transport serve as a potential contamination source.[2,19] A closed manufacturing system helps to ensure that all surfaces in direct contact with the blood remain sterile and pyrogen free throughout blood manufacturing and storage. Closed collection, processing, and storage kits (also known as *disposables*) have been developed as an effective means of preventing the introduction of environmental pathogens.

Whole blood collection and storage kits incorporate, at a minimum, a 16-gauge phlebotomy needle, tubing, and a primary collection bag with an anticoagulant-preservative solution. For routine donations, a collection kit that contains a 450-mL or 500-mL primary bag is used to accommodate the standard whole blood collection. In addition, 250-mL and 450-mL bags can be used for special collections, such as autologous donations and low-volume units. In the United States, 250-mL collection kits are not licensed for volunteer or directed donation and must be reserved for autologous donors. Depending on the kit manufacturer and processing requirements, the integrated system may include one or more of the following: a diversion pouch, satellite bags for component preparation (i.e., double, triple, or quad packs), a bag with additive solution for red blood cell (RBC) storage, and an in-line leukoreduction filter.

Some collection kit accessories are provided separately and can be attached to the primary collection kit through a sterile connection device (SCD), which applies a sterile weld between two pieces of compatible tubing. To effectively maintain the integrity of the closed system, SCDs must be used as recommended, and the sterile weld must be checked for defects. If there is a defective connection, the system is considered open, and the product expiration is affected.[20] Guidelines for the proper use of SCDs are provided by the FDA in a guidance document.[21]

Manufacturers of apheresis equipment supply customized apheresis collection and storage kits that meet the unique specifications of each apheresis instrument and type of component collection. In general, apheresis disposables incorporate a specialized, integrated system of tubing and bags that allows for closed, sterile collection. Similar to whole blood collection kits, the type of blood bags in an apheresis kit depends on the type of component collected and the component's storage requirements.

Diversion Pouches

Diversion pouches have been recently introduced as a means to help further reduce bacterial contamination from donor skin flora. Even with proper skin antisepsis during donor preparation, residual deep-seated bacteria can be introduced into the collected blood through coring of the skin during venipuncture.[22] Several studies have shown that the collection of the initial volume of blood into an in-line diversion pouch can provide an additional safeguard against skin flora contamination. By using an in vitro model with the common skin contaminant *Staphylococcus aureus*, Wagner and colleagues[23] demonstrated that the diversion of the first 21 mL to 42 mL of blood flow results in a 95% to 98% reduction of bacteria in the final collection volume. Another study by de Korte and associated[24] showed a significant overall decrease in *Staphylococcus* species in whole blood collections (0.14% to 0.03%, $p = 0.015$) with the use of a 10-mL diversion system. Several manufacturers offer an FDA-approved, in-line diversion pouch as part of a blood collection kit. In addition to reducing bacterial contamination, these pouches have been designed to accommodate sufficient volume for donor sampling for required and standard infectious disease and serological testing.

Blood Bag Plastics: Polymers and Plasticizers

All blood collection and storage systems are made of disposable plastic. There are many types of plastics available; however, only a few plastic materials meet the specifications for blood processing and storage. The fundamental structure of a plastic is the polymer, which is a repeatedly linked chain of a simple base chemical called a *monomer*.[25] To be

functional, polymers require additives, such as plasticizers, to increase flexibility and stability. In general, the unique properties of each type of plastic are determined by the monomer, chain length, and additives.

Plastic materials for blood bags must have particular qualities. These qualities include, depending on the bag's intended use, adequate flexibility and strength to withstand centrifugation and handling; temperature resistance for both steam sterilization and freezing; limited toxicity to the transfusion recipient; compatibility with cells and plasma to reduce component adulteration; selective permeability for cellular gas exchange; water and pathogen impermeability; and transparency for effective product visualization.[25] Of all available polymers, polyvinylchloride (PVC) has been shown to be the most compatible with component manufacturing. During the past 50 years, most innovations in blood bag materials have focused on improvements in PVC with the incorporation of different plasticizers. The two most common plasticizers in current use for PVC blood bags are di-2-ethylhexylphthalate (DEHP) and tri-2-ethylhexyl trimellitate (TEHTM).[25] In addition to increasing PVC flexibility, plasticizers act to improve gas exchange across the bag barrier and help to stabilize the RBC membrane during storage.

Effective gas exchange is especially important for maintaining platelet viability during storage. Platelets are particularly sensitive to an acidic environment, with major shape changes and cell death occurring at a pH less than 6.0.[26] In a gas-impermeable container, the high metabolic rate of room-temperature platelets causes the pH to drop rapidly as lactic acid accumulates with oxygen consumption and compensatory anaerobic metabolism.[27] To meet the need for enhanced platelet viability and longer storage, platelet storage bags in current use ("second-generation bags") are made with selectively permeable plastics, thinner walls, and increased surface area for better gas exchange.[28–31] In addition to PVC-based bags, a polyolefin-based bag has been shown to effectively maintain platelet viability and is approved by the FDA for platelet storage.[28]

For RBCs, in addition to the benefit of improved gas exchange, plastic containers also appear to improve RBC stability during storage. This property was initially suggested by early work that showed significantly reduced hemolysis and osmotic fragility of blood stored in plastic bags compared to blood stored in glass containers.[32] It was later shown that RBCs stored in the presence of the plasticizer DEHP have improved in vitro survival,[33] decreased microvesicle formation,[34] and better post-transfusion survival[35] compared to RBCs stored in the absence of DEHP. Additional studies have shown that DEHP, a highly lipophilic compound, leaches out of PVC-DEHP containers and into the RBC membrane during storage,[36,37] thus stabilizing the RBC membrane and prolonging RBC survival. Given the superior quality of RBCs stored in DEHP and the lack of a commercially available alternative, PVC-DEHP is currently the only plastic used for RBC storage.[25]

The use of DEHP is not without concern, and the relative safety of PVC-DEHP has been questioned for the past 20 years.[38] Early work by Jacobson and colleagues,[39] using a rhesus monkey chronic platelet transfusion model, suggested that the chronic transfusion of DEHP-stored platelets is associated with an increased rate of hepatic dysfunction and liver histopathology compared to chronic transfusion with non–DEHP-stored platelets. A postmortem study by Hillman and coworkers[40] also showed accumulation of DEHP in the tissues of critically ill human neonates who had received blood products. Further studies of DEHP toxicity in rodents have suggested the potential for developmental and reproductive effects in humans, although human toxicity has not been conclusively proven.[41] The National Toxicology Program's Center for Risks to Human Reproduction provides a recent extensive review of DEHP toxicity studies and suggests the need for additional evidence to conclusively prove DEHP's toxic effects.[41] As stated in the report, the primary concern is the effect of DEHP in neonates and children who are chronically transfused or undergo blood volume exchange and are exposed to a high cumulative dose of DEHP. For example, with a single-procedure double-volume exchange in a neonate, the dose of DEHP is approximately 1800 μg/kg bw/day; and for a neonate treated with replacement transfusions, the average dose is 300 μg/kg bw/day. For comparison, the current maximum allowable occupational inhalational exposure to DEHP in an adult is 700 μg/kg bw/day. At this time, the potential toxicity of DEHP is still unclear, and currently, DEHP remains the most common plasticizer used for blood bags.

Anticoagulant and Preservative Solutions

Under storage conditions, RBCs show predictable, time-dependent adverse changes, which together are known as the *red cell storage lesion* (Table 12–1). Key consequences of the storage lesion are a reduction in post-transfusion RBC survival and impairment of oxygen transport, which are effects that lead to an overall decrease in transfusion efficacy.[42] Although the cellular and molecular events that lead to the storage lesion have not been completely elucidated, certain principles are known. RBCs are anucleate, and thus, they lack the synthetic machinery to renew structural proteins and enzymes. Without replacement of structural proteins and enzymes to maintain the RBC membrane and metabolic machinery, RBCs undergo senescence during storage. RBCs are also devoid of mitochondria, the organelle required for oxidative phosphorylation. To produce ATP for cellular energy, RBCs rely on anaerobic metabolism (the Embden-Meyerhof pathway), which requires a continuous supply of glucose and adenine and produces large quantities of lactic acid and hydrogen ions.[43] With acid accumulation and decreasing pH, enzymes and structural proteins undergo changes that compromise cell metabolism and stability.

In addition to these structural and metabolic changes, RBC function is affected with storage. To effectively deliver oxygen, RBCs require sufficient levels of 2,3-diphosphoglycerate (2,3-DPG). By competing with oxygen for hemoglobin binding sites, 2,3-DPG acts to displace oxygen from hemoglobin, thus making the oxygen more readily available for tissue uptake. During storage, the concentration of 2,3-DPG in RBCs declines. With low levels of 2,3-DPG, hemoglobin binds oxygen more avidly, and the oxygen delivery function of the stored RBCs is reduced. Within approximately 3 weeks of storage, RBC 2,3-DPG concentration falls to below 10%.[44] This effect is reversed after transfusion, however, because the transfused RBCs replenish 2,3-DPG within 24 to 48 hours in circulation.[45,46]

Two important methods for RBC preservation are refrigeration and the use of supplemental anticoagulant-preservative solutions. With refrigeration (1°C–6°C), the metabolic rate of RBCs is reduced significantly, and senescence is delayed.[47] However, to effectively extend red cell storage beyond 5 days, a preservative solution is necessary.[48] The efficacy of a preservative in maintaining stored red cells is

Table 12–1 Biochemical Changes of Stored Red Blood Cells (RBC Storage Lesion)

‡Values for plasma hemoglobin and potassium concentrations may appear somewhat high in 35-day stored RBC units; the total plasma in these units is only about 70 mL. From American Association of Blood Banks. Technical Manual, 14th ed. Bethesda, MD, AABB, 2002.

determined by assessing the preservative-stored RBC viability post-transfusion. Specifically, in order to meet established regulations and standards, 75% of the stored RBCs must remain in circulation at 24 hours after transfusion,[42] as measured by an in vivo ^{51}Cr red cell radiolabeling and transfusion method.[49]

The common anticoagulant-preservative solutions used in transfusion practice are acid citrate dextrose (ACD-A), citrate phosphate dextrose (CPD and CP2D), and citrate phosphate dextrose adenine CPDA-1. RBCs suspended in these solutions are stored at a hematocrit (Hct) between 70% and 80%. As seen in Table 12–2, anticoagulant-preservative solutions vary in content and the approved length of RBC storage, with the RBC storage limit for CPD and CP2D at 21 days and CPDA-1 at 35 days. Additive solutions (AS-1, AS-3, AS-5), discussed in the following section, are approved for RBC storage up to 42 days.

Each component of the preservative solution has a specific metabolic support function. Dextrose and adenine serve as substrates for ATP production, and phosphate acts as a pH buffer and substrate for 2,3-DPG formation. For a whole blood collection kit, the volume of the anticoagulant-preservative solution is specific for the collection volume. For a 450-mL primary collection bag, the anticoagulant-preservative solution is 63 mL, and for a 500-mL primary collection bag, the solution volume is 70 mL. If the whole blood collection is less than 300 mL, the volume of anticoagulant-preservative solution must be adjusted to maintain an approximate anticoagulant-to-blood ratio of 1.4:10.

To extend the expiration time to 42 days, RBCs are suspended in an additive solution (100 mL) that is transferred to the primary bag after the plasma is expressed from the whole blood collection. Additive solutions decrease in vitro hemolysis by stabilizing the RBC membrane, either through the action of mannitol or citrate.[42] With an approximate hematocrit of 60% for additive-stored RBCs, these solutions also act to enhance transfusion flow and reduce product administration time by decreasing the viscosity of packed RBCs. Listed in Table 12–3, the currently approved additive solutions include the saline-adenine-glucose-mannitol (SAGM) formulations, AS-1 (Adsol) and AS-5 (Optisol), and a non–mannitol-based solution, AS-3 (Nutricel). AS-1 and AS-5 can be coupled with any of the anticoagulant-preservative solutions in a whole blood collection system; however, AS-3 requires supplemental glucose and must be paired with CP2D for a whole blood collection kit.[43]

Current efforts to develop media that prolong RBC storage beyond 6 weeks have led to a new generation of experimental additive solutions (EASs) that are under investigation.[50-52] Although most EASs increase storage to between 7 and 10 weeks, reports by Meryman and associates[53] and Hess and associates[54] provide evidence for effective liquid RBC storage

for up to 12 weeks. The potential benefits of prolonged storage with EASs include reduction of allogeneic RBC outdate rates; decreased donor exposure for premature infants who require repeat, small-volume maintenance transfusions; and an increased collection window for autologous donors. The primary limitation of these new solutions is the inability to adequately preserve 2,3-DPG levels. Because most RBC transfusions are given between 12 and 21 days of storage, the value of extended RBC storage for routine transfusion practice is debatable; however, extended storage may be of benefit in rural outposts and military settings.[54]

As previously mentioned, although 2,3-DPG levels replenish within 48 hours of transfusion, stored RBCs older than 2 weeks have reduced oxygen transport function immediately after transfusion. This property of "older" RBCs may have implications for effective resuscitation of certain patients with more urgent or greater oxygen delivery needs, such as those in cardiac surgery, trauma, massive transfusion, and critical care settings.[55-59] Thus, research efforts for improving additive solutions continue to focus on methods for improving 2,3-DPG preservation. A recent report by Högman and colleagues[60] provides promising data for a modified EAS, Erythro-Sol 2, which maintains RBC 2,3-DPG levels at a normal level over a 2-week storage period. Another study by Kurup and coworkers[61] compared the RBC storage properties of SAGM and a modified SAGM solution. Although the SAGM showed a 99% decrease in 2,3-DPG levels by day 28, the modified SAGM maintained day 28 RBC 2,3-DPG levels near baseline, with an overall decrease of less than 1%. Although EASs have received approval in Europe,[62] an extended storage solution is not currently approved in the United States.

Whole Blood Collection

Donor Requirements

In addition to enhancing transfusion recipient safety, some of the donor eligibility requirements for allogeneic and directed whole blood donation are established for the purpose of enhancing donor safety and include limits for donor volume deficit, weight, hemoglobin, and donation frequency. Studies of controlled blood loss in normal, healthy adult volunteers indicate that up to 15% of a donor's blood volume (BV) can be safely removed without significant physiologic signs or symptoms.[63,64] Thus, the maximum allowable intravascular volume deficit for a single donation is 10.5 mL/kg (15% BV), which includes the volume for test samples and in residual tubing.[65] In the United States, the standard volume for a whole blood donation is 450 mL to 500 mL ± 10%. With test samples, the entire collected blood volume for a typical donation is approximately 525 mL. Therefore, the standard minimum donor weight for routine whole blood donation is 50 kg or 110 lb (10.5 mL/kg × 50 kg = 525 mL). To prevent overcollection, a practical method for monitoring volume during donation is to weigh the whole blood unit. For a normal donor hematocrit, the specific gravity of whole blood is 1.053,[66] so a commonly used conversion factor to calculate the collected volume (mL) from the unit weight (g) is 1.06 g/mL.

Another physiologic consequence of blood donation is the temporary reduction of donor RBC mass. Because most of the body's iron is carried in RBCs, loss of RBC mass after repeated donations can lead to anemia, especially in premenopausal females.[67] To reduce the risk of anemia, an allogeneic donor is required to have a hemoglobin level of greater than or equal to 12.5 g/dL (Hct 38%) and is limited to donating once every 8 weeks, unless examined and cleared by a physician to donate more frequently, which in practice occurs only in unusual situations with directed donors.

Donors with Hereditary Hemochromatosis

Whole blood collected for the purpose of therapeutic phlebotomy must be labeled with the donor's disease if the blood is used for transfusion.[68] Although therapeutic collections from otherwise healthy individuals with hereditary hemochromatosis are considered safe for allogeneic transfusion, these units are often rejected by hospital transfusion services due to the required disease label.[69] Recently, however, the FDA introduced the option for a variance that allows collection facilities to exclude the disease designation from whole blood units obtained by therapeutic phlebotomy from individuals with hereditary hemochromatosis.[70] Under the variance, the donor must meet the standard allogeneic donor suitability requirements, and the collection facility must not charge a fee for the collection. In addition, to collect from a donor more frequently than every 8 weeks, a physician prescription for therapeutic phlebotomy or a physical exam and physician's certification of good health is required.

Collection Procedure

Phlebotomy is performed using the integral donor needle supplied with the sterile collection and storage kit. Immediately prior to phlebotomy, a tourniquet or blood pressure cuff is applied and is kept in position throughout collection. To limit trauma to subcutaneous tissue, a single venipuncture is performed, and the needle is secured to prevent movement or displacement. If signs of an arterial puncture are present, such as rapid filling of the blood bag (<4 minutes) and bright red, pulsating blood flow, the procedure should be immediately discontinued, the needle removed, and extended pressure applied.[7]

Because the internal surface of the collection tubing is not filled with an anticoagulant, adequate blood flow must be maintained to prevent coagulation factor activation and

clotting prior to the blood entering the primary collection bag. As the blood enters the primary container, it should be mixed frequently with the anticoagulant to avoid clot formation. With sufficient flow, the duration of a whole blood collection is approximately 10 minutes. The effect of donation time on whole blood–derived plasma and platelets does not appear to be significant until the donation exceeds 15 minutes.[71,72] For whole blood collections that exceed 15 minutes, data suggest increased thrombin generation in the plasma and decreased platelet counts in the platelet concentrates. Although there is no FDA regulation for maximum collection time, based on these data, it is recommended that whole blood collections that exceed 15 minutes be restricted to red cell production and not be used for platelet concentrates or plasma components for transfusion.[73]

Automated Apheresis Collection

Apheresis is the process by which a desired component of whole blood is separated and collected, and the unselected constituents of whole blood are returned to the donor. The types of blood components collected by apheresis of volunteer donors include plasma (plasmapheresis), platelets (plateletpheresis), RBCs (erythrocytapheresis), and leukocytes (leukapheresis). Although manual apheresis methods are available, automated apheresis is more convenient and provides better product safety and quality. Hence, manual apheresis is not routinely employed for component collection.

Donation Requirements

In addition to meeting the standard eligibility requirements for allogeneic blood donation, routine apheresis donors must also meet criteria specific for the type of apheresis procedure and frequency of donation. For all apheresis collections, a donor is not eligible if a whole blood donation or equivalent apheresis RBC loss (>200 mL) occurred within the previous 8 weeks, unless the extracorporeal RBC volume during the current apheresis procedure is less than 100 mL.[74–76] If the RBC loss for a single procedure is greater than 300 mL, the donor is deferred for 16 weeks.[76] The collection facility must monitor total annual donor RBC loss from all apheresis and whole blood donations to ensure that the RBC volume does not exceed that allowed for cumulative yearly whole blood donation.[77] Regardless of standard requirements, when a specific component is deemed to be of particular value to a specific recipient (e.g., human leukocyte antigen [HLA]-matched platelets), an otherwise ineligible donor may donate if approved by the medical director.[78]

For automated plasmapheresis, in addition to the routine donor test samples, the FDA requires the collection of a blood sample on the day of the first physical exam for donation or on the day of the first plasmapheresis procedure.[79] Tests on the sample include a total protein quantification and plasma or serum immunoglobulin composition (e.g., serum protein electrophoresis). Additional donor qualifications are defined by donation interval. "Infrequent" plasmapheresis is performed every 4 weeks or less frequently, and "frequent" plasmapheresis is performed at an interval of 4 weeks, or more frequently.[75] For frequent donors, a serum or plasma protein study is required prior to each donation, and the cumulative results must be evaluated by a qualified, licensed physician within 21 days of the sample draw to determine donor acceptability for subsequent plasmapheresis collections. If the total protein level is less than 6 g/dL or the immunoglobulin composition is abnormal, the donor is ineligible until the values normalize. Frequent donors can donate a maximum of 2 times in a week, as long as the collections occur at least 2 days apart. The FDA-approved volume limits for a single, automated plasma collection are specific for each apheresis instrument and provided by the instrument manufacturer.[80] The annual limits for maximum donated plasma volume are 12 liters (110 to 175 lb) and 14.4 liters (>175 lb).[75]

For plateletpheresis, a platelet count is not required for the first collection and is only required for subsequent collections if the donation interval is more frequent than every 4 weeks.[81] If the platelet count drops below 150,000/μL, the donor usually is temporarily deferred until the count rises above 150,000/μL. Regardless of platelet count, a donor who has ingested aspirin or aspirin-containing medications within 36 hours prior to collection is ineligible for plateletpheresis donation, because aspirin irreversibly inhibits platelet function. The frequency limits for plateletpheresis are two collections in a 7-day period with at least a 48-hour interval between collections, and a maximum of 24 collections performed in a year.[74] The total volume limits (excluding anticoagulant) for a single, automated plateletpheresis collection are 500 mL (110 to 175 lb) and 600 mL (>175 lb). As with automated plasma collection, the annual volume limits for automated plateletpheresis are 12 liters (110 to175 lb) and 14.4 liters (>175 lb).

At the time of this writing, the FDA has posted a draft guidance document for automated platelet collection, and if accepted for implementation, it will replace previous guidelines.[82] Proposed changes to the previous guidelines include additional eligibility criteria for platelet-inhibiting medications, such as Clopidogrel, Ticlopidine, and NSAIDs, and an extension of the aspirin deferral from 3 days to 5 days postingestion. In addition, because modern apheresis instruments are capable of more than one platelet collection, new recommendations for double and triple platelet donors have been proposed.

Automated RBC apheresis donor requirements, including height, weight, and hemoglobin/hematocrit, are defined for each FDA-approved instrument and provided by the manufacturer. In addition to instrument-specific criteria, there are general donor suitability requirements for automated RBC collections.[76] For single apheresis collections (RBC volume of 200 mL to 300 mL), the requirements are similar to whole blood donation (e.g., limited to 8-week intervals). However, the criteria for double RBC collections (RBC volume > 300 mL) are somewhat different. A donor hemoglobin or hematocrit level is required prior to each donation, as measured by a quantitative method and not by the copper sulfate (CuSO4) method. This preprocedure value, along with the donor's height, weight, and gender, is used to determine a predicted postprocedure hemoglobin or hematocrit for donor eligibility.[76] If a drop in hemoglobin of <10g/dL or in hematocrit of <30% is predicted, the donor should not be considered for a double RBC collection. Instrument manufacturers provide device-specific nomograms and formulae to assist collection facilities with this determination. If a double RBC collection is performed, the donor is deferred from whole blood or apheresis collection for 16 weeks.

Several apheresis devices are capable of collecting multiple concurrent components (see Table 12–4). For multicomponent collection, the donor must meet eligibility and donation frequency criteria for each collected component. In

addition, the combined donor plasma and RBC losses must be determined and must not exceed the device-specific limits approved by the FDA.[83]

Granulocyte collection is a more involved process compared to other automated apheresis donations and necessitates special donor preparation. To obtain sufficient granulocyte dose ($>1.0 \times 10^{10}$), donors are treated with leukocyte mobilizing agents, such as corticosteroids and granulocyte colony-stimulating factor (G-CSF), prior to granulocyte collection (see Chapter 24).[84] Although there are limited data on the long-term effects of mobilization in healthy donors, several studies indicate that in the short-term there is minimal risk, even after repeat donations.[85–87] However, donors often experience side effects, such as headache, bone pain, myalgias, and arthralgias after mobilization, particularly with G-CSF administration. These symptoms are generally transient (<24 hours) and well tolerated by donors.[88] In addition to precollection leukocyte mobilization, an erythrocyte sedimenting agent, such as hydroxyethyl starch (HES), is added during granulocyte apheresis for more effective granulocyte–red cell separation. The addition of HES improves granulocyte yield and reduces donor RBC loss during the procedure.[89] For donors, the disadvantages of HES include the immediate side effects of intravascular volume expansion, such as headache and pulmonary edema, and the potential cumulative toxic side effects, such as severe pruritus and coagulopathy.[90] Because HES persists for weeks to years in circulation,[91,92] the additive volume of HES for a repeat donor must be routinely determined and monitored for cumulative toxic dose.[93] As part of the eligibility assessment for granulocyte donation, donors should be evaluated for medical conditions that may be exacerbated by HES and leukocyte-mobilizing drugs. In addition, donors should receive information about the potential side effects of these drugs as part of the informed consent process. As with other apheresis collections, the standard allogeneic donor eligibility criteria and infectious disease testing requirements apply to granulocyte collection, though the release of collected granulocytes to the transfusing facility often occurs before all test results have been obtained, as these cells lose viability quickly, within 8 to 24 hours of collection. In addition, the automated platelet collection frequency limits and cumulative RBC loss limits apply to granulocyte collection.

Collection Procedure

For automated apheresis, the donor is connected by intravenous access to a programmable device that draws, processes, collects, and returns blood to the donor all in a single donation session. To separate a component, most automated devices employ differential centrifugation, which separates by specific gravity. Instruments that collect by centrifugation are designed to process blood by continuous flow centrifugation (CFC), with an uninterrupted separation and return circuit, or by intermittent flow centrifugation (IFC), with alternating separation and return cycles. The process of cell separation during centrifugation isolates leukocytes for "process leukoreduction" during the apheresis collection. In addition, depending on the manufacturer, the apheresis disposable kit may include an in-line filter for leukoreduction. Leukoreduction can also be performed off-line with a sterile-docked leukoreduction filter. Automated apheresis instruments also differ in terms of required intravenous access (single- or double-arm) and collection capability (single- or multiple-component collection). See Table 12–4 for a summary of current available instruments and collection capabilities. Because each apheresis instrument has a unique design and function, a disposable collection kit that meets the specifications of an individual instrument and type of collection is required.

As with whole blood donation, the maximum extracorporeal blood volume allowed at any time during apheresis is 10.5 mL/kg. Most instruments are equipped with a control panel for the apheresis operator to input donor and collection data, calculate donor blood volume, and monitor fluids and flow rate during the procedure. To maintain relatively constant volume during apheresis, normal saline is often used both to prime the circuit and to balance fluid shifts. A citrate-based anticoagulant, such as ACD-A, is also added to prevent clotting and to maintain extracorporeal flow during apheresis. Citrate, which chelates calcium, can cause symptomatic hypocalcemia, which can result in seizures, hypotension, and fatal arrhythmias if left untreated.[8] In practice, these severe reactions are unusual, because early signs of hypocalcemia, such as perioral tingling, are monitored in donors. If signs and symptoms of hypocalcemia are noted, temporary cessation of the procedure and reduction of apheresis flow rate are usually effective.[8] If symptoms persist, oral calcium

supplementation may be given, or with more severe symptoms, an intravenous calcium solution is administered.

Quality control criteria for apheresis component collections are established to ensure consistent and adequate product dose. For apheresis RBCs, the method employed should result in a mean hemoglobin of 60 g in the final product, and at least 95% of the units tested should have a hemoglobin of 50 g.[94] For leukoreduced, apheresis red cells, the procedure should result in a mean hemoglobin of 51 g, with fewer than 5×10^6 residual white cells in the final component, and 95% of the units tested should have a hemoglobin of 42.5 g.[95] For plateletpheresis quality control, the method should result in a final platelet count of 3×10^{11} in at least 90% of the units tested, and a residual white cell count of fewer than 5×10^6 in 95% of the units tested.[95]

COMPONENT PREPARATION AND STORAGE

Components are prepared from the processing of a whole blood donation or via automated apheresis collection methods, as just described. Component preparation from whole blood entails distinct manufacturing steps for collection, transportation, and separation, each of which involves unique logistical issues. With automated apheresis, the whole blood collection and component separation steps are integrated into a single process, as described in the previous section.

After collection and separation, individual components can be further modified by leukoreduction, irradiation, or washing to reduce the likelihood of certain transfusion-related complications. Each component and modified component has specific processing, transportation, and storage requirements, established to optimize product quality, safety, and therapeutic efficacy. Table 12–5 provides a summary of components, modified components, and manufacturing requirements.

In the following sections, component preparation, modification, and storage are discussed. The clinical and therapeutic aspects of blood transfusion are presented in greater detail in the dedicated chapters of this textbook.

Whole Blood Processing

With the advent of component therapy, the use of whole blood for transfusion in the United States has become uncommon. Whole blood is still reported to be a replacement for massive blood loss, such as in trauma and transplant cases.[96] In practice, however, intravenous fluids and blood components serve as the standard therapy for massive resuscitation, and whole blood is rarely used for this purpose. The primary exception is autologous blood, which, for simplicity, is often transfused as whole blood. Currently, the primary purpose of whole blood is as source material for blood component preparation.

For collection facilities, the logistics of whole blood processing depend on the components that are planned to be produced from the whole blood unit. If the whole blood unit is to be processed into plasma and RBCs only, the unit is transported on ice; however, if the whole blood unit is intended for platelet production, then the unit is maintained at room temperature until after separation of the platelet-rich plasma from the RBCs.

For plasma and RBC production, the unit is immediately stored at 1°C to 6°C or transported in a refrigerated system that cools the unit toward the range of 1°C to 10°C to maintain the optimal storage temperature for RBCs. If fresh frozen plasma (FFP) is to be produced, the plasma is separated from the whole blood unit within 8 hours of collection and stored in a freezer at −18°C or colder. A whole blood unit intended for *plasma frozen within 24 hours of phlebotomy* (FP24) is processed and frozen between 8 and 24 hours after collection.

In the case of platelet production, refrigeration leads to changes in the platelet membrane that result in poor in vivo platelet recovery after transfusion.[97–99] Thus, if the whole blood unit is intended for production of a platelet concentrate, then the unit is transported in a container capable of maintaining a temperature as close as possible to the optimal temperature range for platelet viability, 22°C to 24°C.[98] At the component preparation laboratory, the whole blood unit is processed to form a platelet concentrate within 8 hours of collection, and the remaining RBCs are then immediately refrigerated.

In addition to whole blood transport and storage, collection facilities must take into account the whole blood separation method to be employed when planning for component preparation. Whole blood is separated by differential centrifugation based on the specific gravity (relative density) of the blood constituents. The relative density of blood constituents ranges from most dense to least dense, as follows: RBCs, white blood cells (WBCs), platelets, and plasma. The degree of separation and component yield depend primarily on the centrifuge rotor size, speed (*g*- force or rpm), and spin time.[100] A temperature-controlled centrifuge is required to maintain the proper temperature range for the specific type of component being prepared.

The following general methods are used in the United States for whole blood separation. If a whole blood unit is intended for platelet production, the centrifuge temperature is set at 20°C, and a *soft spin* (low *g*- force) is used to separate the whole blood into platelet-rich plasma (PRP) and RBCs. The PRP is then manually expressed with a spring-loaded plasma expresser, through a top port of the primary bag into a satellite bag. The remaining RBCs in the primary bag are refrigerated at 1°C to 6°C. The PRP is further processed at 20°C by a *hard spin* (high *g*- force) to separate the plasma from the platelets. This method of platelet concentrate production is often referred to as the *PRP method*, as opposed to the *buffy coat method* used in European countries.

If the whole blood is not intended for platelet production, the unit is centrifuged at 4°C with a hard spin to separate the whole blood into a platelet-poor plasma (PPP) layer, a buffy coat layer containing platelets and WBCs, and a packed RBC layer. The PPP is then expressed into a satellite bag, leaving the majority of the platelets and WBCs with the RBCs in the primary bag. The RBCs are then immediately refrigerated at 1°C to 6°C.

Pooled Buffy Coat Method

In most European countries and Canada, the buffy coat method is applied to the processing of whole blood for platelet production. With this method, a specialized primary collection bag with ports on the bottom and top, referred to as the *bottom-and-top system* (BAT), is used. A whole blood unit is first centrifuged to produce a buffy coat (platelets and WBCs). With a semiautomated extractor, plasma is then

From American Association of Blood Banks. Standards for Blood Banks and Transfusion Services, 21st ed. Bethesda, MD, AABB, 2002.

expressed out of the top port, and the RBCs are expressed out of the bottom port.[101] The buffy coat platelet concentrate (BC-PC) remaining in the primary bag contains the majority of platelets and WBCs, along with approximately 30 mL of plasma and 30 mL of the RBCs. A pool of BC-PCs is prepared by suspending 4 to 6 units in a platelet additive solution. The BC-PC pool is centrifuged, and the platelet-rich supernatant is passed through a leukoreduction filter and stored.[102] With a pool of 6 BC-PC units, this method will result in more than 3×10^{11} platelets in the final product greater than 75% of the time.[103] Compared to the PRP method, advantages of the BC-PC method include greater plasma volume for plasma components, the ability to perform bacterial testing on stored pools (likely increasing the effective and allowed utilization of these components to 6 or 7 days), and improved metabolic stability of the platelets.[102] The disadvantage of this method is the increased RBC loss (10% to 15% loss) that occurs during processing.[102] An automated method for BC-PC processing is now available that results in increased efficiency, more consistent product volume, and better platelet yield than the manual BC-PC method.[104]

Red Blood Cells

The primary indication for RBC transfusion is the restoration of oxygen-carrying capacity in such conditions as blood loss, anemia, or hemoglobinopathy. RBCs are prepared either by whole blood processing (red blood cells) or by automated erythrocytapheresis (apheresis red blood cells). Often, RBCs are further modified by leukoreduction to reduce the risk of cytomegalovirus (CMV) transmission, alloimmunization, and febrile nonhemolytic transfusion reactions. For special circumstances, RBCs can be irradiated to prevent graft-versus-host disease (GVHD) or washed to prevent severe allergic reactions. For routine storage, RBCs are refrigerated between 1°C and 6°C and stored for 21 days (CPD, CP2D), 35 days (CPDA-1), or 42 days (AS-1, AS-3, AS-5). RBCs that have passed the expiration by up to 3 days can be rejuvenated for immediate transfusion or frozen storage.

Rejuvenated Red Blood Cells

Within the first 2 weeks of refrigerated storage, RBC ATP and 2,3-DPG are depleted.[43] To increase intracellular ATP and 2,3-DPG to normal or above-normal levels, refrigerated RBCs can be *rejuvenated* through a treatment process with the FDA-approved solution Rejuvesol (enCyte Systems, Braintree, Mass.). This rejuvenating solution contains the substrates inosine, adenine, phosphate, and pyruvate for RBC ATP and 2,3-DPG biosynthesis. CPD and CPDA-1 RBCs are approved for rejuvenation up to 3 days after expiration. After rejuvenation, CPD and CPDA-1 RBCs can be stored in the frozen state for up to 10 years, or they can be transfused within 24 hours of rejuvenation. CPD/AS-1 (Adsol) RBCs are approved for rejuvenation and cryopreservation within the 42-day storage period and may be stored in the frozen state for up to 3 years. As opposed to CPD and CPDA-1 units, CPD/AS-1 units are not approved for rejuvenation after expiration or for same-day transfusion after rejuvenation. In addition, the rejuvenation of RBCs stored in an additive system other than CPD/AS-1 (i.e., AS-3 or AS-5) is not currently approved by the FDA. Because rejuvenation early in storage results in excessive 2,3-DPG levels that can potentially impair the oxygen delivery function of the transfused cells in vivo,[105] it is not recommended to rejuvenate RBCs that have been in refrigerated storage less than 6 days.[106]

For rejuvenation of a single unit of stored RBCs, a 50-mL vial of rejuvenating solution is added through a sterile, disposable, Y-type connection and transfer set supplied by the rejuvenating solution manufacturer. Once suspended in the rejuvenating solution, the unit is sealed in a waterproof, double plastic bag overwrap and incubated in a 37°C water bath for 60 minutes. After rejuvenation, the RBCs are prepared for same-day transfusion (CPD and CPDA-1 units) or processed for frozen storage (CPD, CPDA-1, and CPD/AS-1 units).

For same-day transfusion, the rejuvenated unit is immediately washed with an unbuffered saline solution in an approved cell washer to remove the residual metabolites hypoxanthine, uric acid, inosine, and inorganic phosphates prior to transfusion.[107] Outdated, rejuvenated, washed RBCs that are stored at 4°C for up to 3 days have been shown to have an approximate in vitro RBC recovery of 95% and a 24-hour, post-transfusion survival rate of greater than 75%.[107] Despite these favorable data, the open washing procedure, which has the potential for pathogen contamination of the product, limits the approved storage of refrigerated, washed, rejuvenated RBCs to 24 hours.

For cryopreservation by freezing, the rejuvenated RBCs in the primary collection bag are not immediately washed, but they are instead further processed for frozen storage. The RBCs are centrifuged to separate the rejuvenating solution, which is then expressed into a transfer bag and discarded. Following separation, the RBCs are immediately prepared with a 40% glycerol solution and stored at −80°C. Prior to transfusion, these rejuvenated, frozen RBCs are deglycerolized and washed. The freeze–thaw–wash cycle results in an approximate in vitro RBC recovery of 90% and a 24-hour post-transfusion survival rate of greater than 75%. As for RBC function, the rejuvenated, frozen, washed units have normal or above-normal 2,3-DPG levels and adequate or improved oxygen delivery.[108,109]

Frozen and Deglycerolized Red Blood Cells

Cryopreservation by freezing slows or suspends most metabolic functions and thus limits cellular deterioration during prolonged storage. When processed correctly, studies of stored, frozen RBCs have shown acceptable post-thaw in vitro viability and function after several decades of storage.[110–113] The major limitation to cryopreservation for RBC storage is the cryoinjury effect that can occur during the freeze–thaw process.[114] To minimize the effects of cryoinjury, a permeable or nonpermeable cryoprotective agent is added to the cell solution prior to cryopreservation. Glycerol, a permeable cryoprotectant, is the recommended cryopreservative for transfusable RBCs, because it is considered to be nontoxic to humans and has proven efficacy.

There are two general methods employed for the preparation of frozen RBCs, the low glycerol/rapid cooling technique and the high glycerol/slow cooling technique. Because glycerolized RBCs are hypertonic and hemolyze on contact with plasma, both freezing methods require a specialized post-thaw–wash procedure to remove excess glycerol (deglycerolization) prior to transfusion.

With the low glyercol/rapid cooling method, which is primarily used by European blood manufacturers, RBCs are suspended in a 15% to 20% weight/volume (wt/vol) solution of glycerol, cooled at a rate of greater than −100°C/min by immersion in −197°C liquid nitrogen, and stored at

temperatures below −150 °C in liquid nitrogen or nitrogen vapor.[115,116] To prepare for transfusion, the frozen RBCs are rapidly thawed in a 42 °C to 45 °C water bath and deglycerolized. Due to the required extreme storage conditions, RBCs frozen with low glycerol are not as amenable to transportation, and thus, they are typically thawed at the storage facility and shipped to the transfusing facility in the liquid state.[117]

In the United States, RBCs that have been in refrigerated storage for 6 days or less or have been rejuvenated are approved for glycerolization and frozen storage. For the high glycerol/slow cooling process, RBCs are prepared with a 40% wt/vol glycerol solution, slowly cooled at a rate of approximately −1°C/min, and stored at −80 °C in metal or cardboard containers in a mechanical freezer. There are two process variations for the 40% glycerol method: the Meryman-Hornblower technique and the Valeri or Naval Blood Research Laboratory (NBRL) technique.[112,118] With the traditional Meryman-Hornblower method, the excess glycerol solution is not removed from the RBCs prior to freezing, so the post-thaw deglycerolization step requires a large-volume wash to remove the excess glycerol. With the Valeri or NBRL variation for glycerolization, the glycerolized unit is centrifuged, and the supernatant glycerol is discarded prior to freezing. Thus, after thawing, there is a smaller volume of glycerol to remove and a less-extensive deglycerolization process compared to the Meryman-Hornblower method.

For transfusion, the frozen RBC unit is initially thawed in a 37°C water bath or dry warmer and then deglycerolized. With the traditional, open method of deglycerolization, the unit is diluted with hypertonic saline, and then washed with approximately 2 liters of 1.6% saline solution. After adequate washing, the RBCs are suspended in isotonic saline for transfusion. Frozen RBCs that have been deglycerolized in an open system are approved for transfusion within 24 hours. The 24-hour expiration of deglycerolized units and the tedious, semiautomated deglycerolization process have presented both logistic and work-flow challenges for the routine use of frozen units.[117] Recently, however, a more efficient, automated, closed glycerolization-deglycerolization system (ACP 215, Haemonetics, Braintree, Mass.) has been approved by the FDA.[119,120] This system utilizes a disposable processing set, sterile connector device, and an in-line 0.22-μ filter to prevent bacterial contamination during processing. After deglycerolization, the processed RBCs are resuspended in AS-3, instead of isotonic saline, and are approved for refrigerated storage up to 14 days.[121] Frozen RBCs glycerolized by the Meryman-Hornblower method cannot be deglycerolized on the ACP 215, because the system in unable to process the larger volume of supernatant glycerol in these units.

Unlike low-glycerol frozen RBCs, RBCs frozen in 40% glycerol are better suited for transport, because these units are more tolerant of temperature fluctuations and can be effectively transported on dry ice.[122] One factor that complicates the transportation of frozen units is the increased fragility of blood bags that occurs at approximately −78 °C, which makes the units prone to breakage.[123] Traditionally, RBCs have been stored in polyolefin bags inside metal containers (Meryman-Hornblower method). With transport, frozen units stored in this manner have an incidence of breakage of greater than 30%.[124] An alternative, improved method for storage and transport, developed at the NBRL, uses specialized PVC-based freezer bags protected in corrugated cardboard holders, which reduces the rate of transportation breakage to less than 3%.[124]

Platelets

Platelet transfusion is indicated for prophylactic or hemostatic therapy in individuals with acquired or congenital thrombocytopenia or thrombocytopathy. Platelet components are prepared from either whole-blood donation or apheresis collection. For whole blood–derived platelets (Platelets), the preparation method must yield at least 5.5×10^{10} platelets per unit in at least 75% of the units tested by the manufacturing facility. With whole blood–derived platelets, typically 4 to 6 units are pooled immediately prior to transfusion, for a dose comparable to a single apheresis-derived platelet unit. For apheresis-derived platelets (Platelets, Pheresis), the collection method must yield at least 3×10^{11} platelets per unit in at least 90% of the units tested by the manufacturing facility. Large-yield plateletpheresis collections can be divided into two separate apheresis-derived platelets units, also known as *splits*, as long as the platelet count in each unit is greater than or equal to 3×10^{11}. The platelet storage conditions, such as plasma volume, agitation, and temperature, must be optimized to maintain an adequate pH of greater than or equal to 6.2 in 90% of the units tested at the end of the approved storage period. As with RBCs, platelet components are often modified by leukoreduction, and for special conditions, platelets can be further modified by irradiation or washing. In addition, apheresis-derived platelets can be cross-matched or HLA-matched for alloimmunized individuals who exhibit poor platelet increments with random platelet transfusions.

Compared to other components, platelets are more sensitive to variable storage conditions. Although refrigerated or frozen storage would seem ideal for slowing cellular deterioration and retarding bacterial growth, cold storage of platelets results in significantly worse post-transfusion in vivo survival relative to room temperature–stored platelets.[97–99] Furthermore, platelets that remain undisturbed during storage are less efficacious than platelets that are agitated on a horizontal rocker, a process that helps ensure optimal gas exchange and maintenance of pH.[125] Thus, for optimum storage, platelets must be gently agitated and maintained at a temperature range from 20 °C to 24 °C. During transport, the period of time that platelets remain without gentle agitation should not exceed 24 hours, because interruption of agitation for greater than 1 day results in significant damage to the component.[126]

A major challenge with platelet storage is that the room temperature environment and nutrient-rich plasma favor bacterial proliferation.[127] To reduce the risk of significant bacterial burden, the approved storage period for platelets is limited to 5 days after collection,[128] even though platelets stored for longer periods show acceptable in vivo survival.[31,129] Even with 5-day storage, bacterial contamination of platelets with subsequent transfusion-related bacteremia or sepsis had been a leading cause of transfusion morbidity and mortality.[1] To address this issue, in the 23rd edition of the *Standard for Blood Banks and Transfusion Services*, AABB introduced a standard for blood establishments to have methods in place that limit and detect bacterial contamination of platelets.

Given the nonspecific nature of the standard, many methods are employed for bacterial testing, including Gram stain or bacterial culture, point-of-care testing by pH/glucose determination, and visualization of a lack of swirling, which is a sign of nonviable platelets.[1] A major limitation of the

nonculture techniques is the lack of sensitivity (10^6 to 10^7 CFU/mL) compared to bacterial culture systems (10^2 to 10^3 CFU/mL or less).[130–133] Consequently, more false negatives should be expected with nonculture systems. Although more sensitive, the bacterial culture method has the limitations of a larger volume of sample required for testing and a longer wait for test results. In the case of the latter limitation, the platelet unit may be distributed and transfused prior to the reported culture result, so the bacterial status at the time or point of transfusion may be unknown. Typically, point-of-care methodologies are more commonly employed for whole blood–derived platelets, because the volume necessary for bacterial culture constitutes a more significant loss to this smaller-volume platelet product. Apheresis-derived platelets, as a larger-volume product, are more amenable to sampling for bacterial culture, and thus are more often tested by the bacterial culture method, using a sample obtained within 24 to 48 hours of storage. With all methodologies, if a true positive result is obtained, the facility is obligated to quarantine the product, identify the contaminating organism, and if already distributed, notify the customer and retrieve the product if not transfused. If the product has been transfused, the clinical service must be notified for proper assessment and treatment of the transfusion recipient.

Extended (7-Day) Platelet Storage

Room temperature platelets have been stored for up to 2 weeks with acceptable therapeutic efficacy.[102] Advantages of extended storage of platelets are improved logistics, increased inventory flexibility, and decreased cost associated with reduced outdate rates.[134] Although 7-day storage was previously approved by the FDA in the 1980s,[31] concern about the increased risk of transfusion-related sepsis with prolonged storage at room temperature led the FDA to limit platelet storage to 5 days. However, with the increased sensitivity of bacterial detection systems for platelet testing, extended storage of platelets has again become a possibility.[133,135] The FDA's position on 7-day platelet storage is currently in evolution. In 2003, the FDA approved, with restrictions, the use of specific plateletpheresis collection and storage systems for 7-day storage of platelets (COBE Spectra Apheresis System and Trima Automated Blood Collection System, Gambro BCT, Inc., Lakewood, Colo.). At this time, facilities cleared by the FDA for 7-day storage must comply with a specific protocol for bacterial testing, and approved facilities must participate in a postmarket surveillance study of the applied protocol.[136]

Prestorage Pooling of Platelets

Studies of prestorage pooled, whole blood–derived platelets show satisfactory in vitro and in vivo properties.[137–139] Although a common practice in Europe with buffy coat platelets, prestorage pooling of whole blood–derived platelet units has not been approved in the United States due to concerns about increased risk of bacterial growth in prestorage platelet pools.[140] With the introduction of required bacterial testing of platelets in the United States, it has become apparent that the most sensitive bacterial detection methods are based on automated bacterial culture. Given the relatively large sample volume required for bacterial culture and the increased number of units to test for a single transfusion, such methods are not routinely applied for bacterial testing of whole blood–derived platelets. Typically, due to these constraints, less sensitive methods are employed for bacterial testing of whole blood–derived versus apheresis–derived platelets. Prestorage pooling of whole blood–derived platelets provides sufficient sample volume for more sensitive automated bacterial culture methods, thus increasing the likelihood of bacterial detection and improving the safety of whole blood–derived platelets. Consequently, in the United States there is renewed interest in prestorage pooling of whole blood–derived platelets.[141–143] Recently, the FDA approved a system for prestorage leukoreduction and pooling of whole blood–derived platelets that contains an integrated bacterial culture system for automated bacterial detection (Acrodose PL, Pall Corporation, East Hills, NY). With improved technology, the availability and use of prestorage pooled platelets in the United States is likely to increase.

Plasma

Plasma components are obtained by separation from a centrifuged whole blood unit, from a plasmapheresis donation, or as a by-product of plateletpheresis. After collection, plasma can be processed as components for transfusion (FFP and PF24) or as source material for further manufacture (recovered plasma and source plasma) into injectable products (i.e., plasma derivatives) or noninjectable products (i.e., reagents). In general, plasma from a healthy blood donor contains normal levels of proteins, immunoglobulins, and coagulation factors. However, plasma units can vary somewhat in content and appearance based on the donor's diet, medication intake, and physiology. For example, plasma from female donors on estrogen-based contraceptives or hormone replacement therapy can appear green due to an estrogen-related elevation in ceruloplasmin levels.[144,145]

As a transfused product, plasma components primarily serve as a source of coagulation factors and are indicated in the management of coagulopathies associated with liver disease, warfarin therapy, disseminated intravascular coagulation, massive transfusion, and congenital factor deficiencies.[146,147] In addition, plasma components are used as replacement fluids during therapeutic plasma exchange.

Plasma Components for Transfusion: FFP and PF24

FFP and FP24 are indicated for the treatment of disorders of secondary hemostasis associated with multiple coagulation factor deficiencies. For most indications, FFP and FP24 are essentially comparable in therapeutic dose of coagulation factors, except that FFP has significantly higher factor VIII activity.[148] Because the activities of coagulation factors in stored plasma are dependent on temperature and length of storage, the processing and storage requirements for FFP and FP24 are established to optimize coagulation factor levels. In general, during refrigerated whole blood storage, coagulation factor levels remain relatively stable for up to 24 hours.[148] However, although remaining within the hemostatic range, factor VIII activity significantly decreases by 20% to 50% within 24 hours of whole blood storage.[149–151] Factor V exhibits variable stability during 24-hour whole blood storage, with some studies showing an insignificant decrease in activity[152] and others reporting a decrease in activity of greater than 10% from baseline.[148,153]

Due to the significant decrease in factor VIII activity between 8 and 24 hours of refrigerated storage, FFP collected in CPD, CP2D, and CPDA-1 is required to be frozen within

8 hours of collection. FFP collected in ACD is required to be frozen within 6 hours of phlebotomy. If maintained at −18 °C or colder, FFP is approved for storage for up to 1 year. If cleared by the FDA, facilities may store FFP for up to 7 years at −65 °C or colder. For plasma processed and frozen within 8 to 24 hours of collection, the component is designated as PF24. PF24 is approved for storage at −18 °C for up to 1 year after collection. During transport, FFP and PF24 are maintained in the frozen state by packaging with dry ice in an insulated container.

For transfusion, FFP and PF24 are thawed between 30 °C to 37 °C in a water bath for approximately 30 minutes or rapidly thawed in an FDA-approved microwave device for approximately 6 minutes.[154,155] Although less expensive than microwave devices, water baths contribute to a longer thaw time compared to microwave devices, which can impact the immediate provision of thawed plasma in situations that require urgent need, particularly in the trauma setting. In addition, although the frozen unit is placed in a waterproof plastic overwrap bag prior to immersion in the water bath, the baths contain nonsterile water, which may contaminate the entry ports of the unit if the unit is not sufficiently protected. Although microwave devices are more sterile and result in a more rapid turnaround time, these devices are relatively expensive. Furthermore, if not properly maintained, microwave devices have the potential to produce temperature "hot spots" in the unit during thawing, which can damage plasma proteins. Once thawed, FFP and PF24 are approved for storage at 1 °C to 6 °C for up to 24 hours. If prepared in a closed system and not transfused within 24 hours, thawed FFP and PF24 can be relabeled as "Thawed Plasma" and stored at 1 °C to 6 °C for up to 5 days. Although prolonged storage of refrigerated plasma is associated with cold activation of the coagulation system and decreased levels of some coagulation factors,[156,157] this has a clinically insignificant effect, as coagulation factor levels remain well within the acceptable range for adequate hemostasis.[150,158]

Plasma for Further Manufacture: Recovered Plasma and Source Plasma

Plasma that is separated from a unit of whole blood up to 5 days after the whole blood unit expiration is labeled as "Liquid Plasma" and stored between 1 °C and 6 °C. Plasma that is separated from a whole blood unit greater than 24 hours after collection and up to 5 days after the whole blood unit expiration is labeled "Plasma" and stored at −18 °C or colder. FFP that has exceeded the 12-month expiration can also be relabeled as "Plasma" and stored at −18 °C for an additional 4 years. Liquid plasma is approved for use up to 5 days after the expiration of the whole blood unit from which it was separated, and plasma is approved for storage up to 5 years from the whole blood collection date. Although liquid plasma and plasma are licensed for transfusion, these products are often relabeled as "Recovered Plasma" and designated for further manufacture. As an unlicensed product, recovered plasma can only be shipped to another manufacturer if the shipping facility has a "short supply agreement" with the receiving manufacturer.[159]

Source plasma is a licensed product that is collected by plasmapheresis for the purpose of fractionation into injectable or noninjectable plasma products. Donors of source plasma must meet the requirements for allogeneic plasmapheresis donors, including infectious disease testing, plasma protein evaluation, and donation interval limitations. The only exception is that donors of source plasma are not required to be tested for human T-lymphotropic virus (HTLV) 1 and 2.[160] In addition, in contrast to allogeneic donors, donors of source plasma are not required to have a negative result for antibody to hepatitis B core antigen (HBcAg).[160] Furthermore, donors that have a reactive serological test for syphilis can undergo plasmapheresis for source plasma only if the donor is being treated for syphilis and the plasma is specifically designated for further manufacture into control reagents for syphilis testing.[161]

Source plasma that is prepared for injectable products must be labeled "Caution: For Manufacturing Use Only." For noninjectable products, the source plasma product must be labeled "Caution: For Use in Manufacturing Noninjectable Products Only."[160] If intended for injectable products, source plasma is approved for storage at −20 °C or colder for up to 10 years.

Cryoprecipitate and Cryoprecipitate-Reduced Plasma

Cryoprecipitated antihemophilic factor (*cryoprecipitate AHF, cryoprecipitate, cryo*) is indicated for the treatment of coagulopathy associated with hypofibrinogenemia, dysfibrinogenemia, factor XIII deficiency, uremic thrombocytopathy, and tissue plasminogen activator (tPA) therapy.[162] Cryoprecipitate is also used in surgical settings as a source of fibrinogen, admixed with thrombin, for topically applied fibrin glue. In the past, prior to the development of pasteurized, purified plasma derivatives and recombinant factor concentrates, cryoprecipitate was a treatment for hemophilia A and von Willebrand disease (vWD). However, given the improved safety, purity, and efficacy of factor concentrates, cryoprecipitate is no longer a first-line therapy for hemophilia A or vWD when appropriate factor concentrates are available. *Cryoprecipitate-reduced plasma* (also called *cryo-poor supernatant*) is employed as a plasma replacement fluid in therapeutic plasma exchange for the treatment of TTP. Cryoprecipitate-reduced plasma is not an FDA-licensed product.

A unit of cryoprecipitate contains the following concentrated, cold, insoluble plasma proteins: fibrinogen (150 mg to 250 mg), factor VIII (80 IU to 120 IU), fibronectin (30 mg to 60 mg), factor XIII (40 IU to 60 IU), and von Willebrand factor (80 IU).[163] At a minimum, a cryoprecipitate unit is required to have a fibrinogen level of 150 mg and a factor VIII activity of 80 IU. To ensure an adequate concentration of plasma constituents, a unit of cryoprecipitate is prepared from an FFP unit that contains a volume of at least 200 mL. The unit of FFP is slowly thawed, in a refrigerator or water bath, to a range of 1 °C to 6 °C. At this temperature, a precipitate of cold, insoluble plasma proteins forms. After centrifugation at 4 °C to concentrate and pellet the insoluble proteins, the supernatant plasma, known as cryoprecipitate-reduced plasma, is expressed into a satellite bag, and approximately 15 mL is reserved for the cryoprecipitate unit. To maintain adequate factor VIII levels, cryoprecipitate must be refrozen within 1 hour of thawing of the FFP unit. For cryoprecipitate-reduced plasma, the unit is required to be refrozen with 24 hours of FFP thawing. Both cryoprecipitate and cryoprecipitate-reduced plasma are approved for storage at −18 °C or colder for up to 1 year from the original collection date.

For cryoprecipitate transfusion, approximately 8 units are thawed in a 30 °C to 37 °C water bath and then pooled into a single transfer bag. The pooled cryoprecipitate product is required to be stored at room temperature (20 °C to 24 °C)

and is approved for administration within 4 hours of pooling. A single unit of thawed cryoprecipitate, stored at room temperature, is approved for use within 6 hours of thawing. Thawed cryoprecipitate-reduced plasma is approved for storage at 1 °C to 6 °C for up to 5 days.

Granulocytes

The general indication for granulocyte transfusion is treatment of a life-threatening fungal and bacterial infection in an individual with severe but reversible neutropenia, typically resulting from myeloablative chemotherapy that has not adequately responded to antibiotic therapy after 48 to 72 hours (see Chapter 24).[84] Granulocytes are collected by leukapheresis from an eligible donor who has received a leukocyte-mobilizing agent, such as corticosteroids and G-CSF, prior to the procedure. Although granulocytes for transfusion are not an FDA-licensed product, AABB requires that a minimum of 1.0×10^{10} granulocytes per unit are present in at least 75% of the products tested. In addition, because a granulocyte component contains greater than 2 mL of red blood cells, the donor and recipient ABO type and crossmatch must be compatible.

Starting immediately after collection, granulocyte function deteriorates rapidly; thus, a granulocyte component should be transfused as soon as possible after collection, usually within 8 to 24 hours.[164] Because granulocyte components contain viable T lymphocytes and are transfused to immunocompromised individuals, all granulocyte products should be irradiated to prevent GVHD. When transported or temporarily stored, the component should be kept at room temperature (20 °C to 24 °C) without agitation.[165] In addition, for obvious reasons, a granulocyte product should not be leukoreduced or transfused through a bedside leukoreduction filter. Although not an FDA-licensed product, granulocytes are considered a "product under development" under 21 CFR 601.21,[166] and thus are exempt from requirements for licensing for interstate transport and may be shipped from one state to another as long as the product is not "introduced into interstate commerce."

Modification Processes

Leukoreduction

Leukoreduction involves the removal of WBCs from cellular components to reduce the risk of HLA alloimmunization, CMV transmission, and febrile nonhemolytic transfusion reactions.[167] Leukoreduction can be performed by filtration prior to component storage (prestorage leukoreduction) or during the transfusion (bedside filtration). For apheresis-derived platelets, leukoreduction is often performed by cell separation during the apheresis collection. For whole blood, whole blood–derived platelets, and RBCs, leukoreduction is performed using third-generation leukoreduction filters, which are commercially available as an integral part of a whole blood collection kit or as a separate, sterilely docked device. This modification process is discussed in detail in Chapter 26.

Quality control standards for leukocyte-reduced components require that 95% of the units sampled contain fewer than 5×10^6 WBCs per unit for apheresis-derived platelets and RBCs and fewer than 8.3×10^5 WBCs per unit for whole blood–derived platelets.[168] In addition, for both apheresis-derived and whole blood–derived RBCs, the RBC loss from filtration must not exceed 15% of the original unit. The most common quality control method employed for white blood cell enumeration is light microscopy using a Nageotte chamber.[169] Although this manual method is relatively inexpensive, it is labor-intensive and results in a high degree of interindividual variation. Automated flow cytometry and microfluorometry hemocytometers provide a more accurate and precise method for WBC enumeration.[170] Although more expensive, automated devices offer greater convenience and are being increasingly employed by blood centers for leukofiltration quality control.

Washing

Washed cellular products are indicated for individuals who have a history of recurrent, severe allergic transfusion reactions.[171] In addition, for neonatal transfusion, washed maternal platelets are indicated for neonatal alloimmune thrombocytopenia (NAIT),[172] and washed RBCs, previously stored in additive solution, have been suggested as an option for neonatal massive transfusion.[173] Cell washing can be performed by manual or automated methods. Automated cell washing devices contain a specialized centrifugation device with fluid input and output channels that remove supernatant waste from the cells and add normal saline (0.9%) solution for cell resuspension. Manufacturers of cell-washing systems provide a customized, disposable processing kit that meets the specifications of the cell-washing device. With a 1-L to 2-L saline wash procedure, greater than 99% of the supernatant plasma is removed from the component, with approximately 90% recovery for washed platelets[174] and 80% to 85% recovery for washed RBCs.[173,175] This modification process is discussed in additional detail in Chapter 29.

Current cell-washing devices operate as an open system, so the expiration of the washed component is affected. For refrigerated, washed red blood cells, the expiration is 24 hours, and for room temperature, washed platelets, the expiration is to 4 hours. The shortened expiration time presents a logistic challenge for washed platelet transfusion, because an additional platelet "rest" step of approximately 1 hour is typically performed prior to release[172]; therefore, the actual allowable time to transfusion is between 2 and 3 hours. Finally, washed components are not FDA licensed, and thus they are not approved for interstate transport.

Irradiation

Irradiation of blood components is performed to prevent transfusion-associated graft-versus-host disease (TA-GVHD), a fatal transfusion complication. TA-GVHD occurs when donor T lymphocytes, present in cellular blood products, engraft, proliferate, and destroy the target organs in a susceptible transfusion recipient. Irradiation of cellular products, with either gamma rays or x-rays, prevents TA-GVHD by damaging donor T-lymphocyte DNA, with resultant inhibition of donor T-lymphocyte proliferation within the recipient.[176]

Blood component irradiation is considered a manufacturing process, so a facility that performs irradiation must be registered with the FDA. Free-standing irradiators used in blood manufacturing contain either a radioactive cesium (^{137}Cs) or cobalt (^{60}Co) source. Because the intensity of the radioactive source decays with time, the dose of radiation to which the blood product is exposed, measured in centiGray (1 cGy = 1 rad), is dependent on the source half-life. Thus,

to obtain a predicted, fixed radiation dose, the radioisotope decay is calculated to determine radiation exposure time. In addition, the irradiator must be recalibrated periodically, semiannually for ^{60}Co irradiators and annually for ^{137}Cs irradiators, to ensure adequate delivered dose.[177] Although a dose of 1500 cGy significantly reduces T-lymphocyte proliferation, a dose of approximately 2500 cGy has been shown to completely inhibit T-lymphocyte proliferation, based on studies using the sensitive limiting dilution assay (LDA).[178,179] Accordingly, quality control standards require that the minimum radiation dose delivered to the component be 2500 cGy, with a minimum dose of 1500 cGy at any point in the blood product. This modification process is discussed in detail in Chapter 28.

Validation of the irradiation process is performed by a dose-mapping procedure, which measures the dose of radiation delivered to specific points over the entire area of a simulated blood product. For dose mapping, a phantom, composed of water or plastic and equipped with strategically placed dosimeters, is positioned inside the irradiation chamber. On irradiation, each dosimeter absorbs a specific dose of radiation, which is then measured and mapped. Available dose-mapping systems for blood irradiators employ one of the following: radiochromic film dosimeters, thermoluminescent dosimeters (TLD chips), or metal oxide semiconductor field effect transistors (MOSFET). Along with dose validation, a process for irradiation confirmation is necessary. This process is performed by affixing a label that contains radiosensitive film to the blood product prior to irradiation. On irradiation, the film changes from transparent to opaque, providing visual evidence that the product was irradiated.

With irradiation, the expiration date and time of granulocytes and platelets are unaffected. However, the shelf life of RBCs is shortened due to irradiation-induced acceleration of adverse storage effects, such as decreased in vivo survival[180,181] and increased potassium leakage.[182] For irradiated RBCs, the expiration date is 28 days from the day of irradiation or the original expiration date, whichever comes first.

LABELING

In 1985, due to concerns about potential transfusion errors related to inconsistent industry labeling practices, the FDA published the "Guidelines for the Uniform Labeling of Blood and Blood Components."[183] Along with specifications for label design, content, and product identifiers, these guidelines introduced to blood manufacturing a machine-readable bar code system, known as *ABC Codabar*, to better facilitate information transfer, product identification, traceability, and trackability. Although ABC Codabar enhanced blood manufacturing efficiency and decreased the likelihood of mistransfusion, the system was limited by the lack of controls for data substitution errors and an inadequate number of codes for newly developed products.[184] Thus, within a few years of ABC Codabar implementation, the need for an improved electronic data management process was recognized. To address this need, the International Society for Blood Transfusion (ISBT) proposed an alternative uniform product coding system, known as ISBT 128, to be managed by the International Council for Commonality in Blood Banking Automation (ICCBBA).

With its advanced coding system using discrete data structures, ISBT 128 is more amenable to automation, new product development, inventory control, global distribution, and future introduction of radio frequency identification (RFID) technology.[184] Both the FDA and AABB endorse the ICCBBA's "United States Industry Consensus Standard for the Uniform Labeling of Blood and Blood Components Using *ISBT 128*," and they have committed to a time line for ISBT 128 implementation by the U.S. blood industry.[185,186] Effective November 1, 2006, the 24th edition of the *AABB Standards for Blood Banks and Transfusion Services* will require accredited facilities to have a written plan for the transition to and implementation of ISBT 128; and effective May 1, 2008, the 25th edition will require accredited facilities to have fully implemented ISBT 128.[186] In addition to blood and blood products, ISBT 128 will be applied to labeling for cellular therapy products and tissues, with an effective implementation date of September 1, 2008.[186] In light of these developments, the following section will provide a general overview of the ISBT 128 labeling system, with reference to ABC Codabar for comparison purposes only. The reader is encouraged to visit the ICCBBA website (http://www.isbt128.org) and the AABB website (http://www.aabb.org) for additional resources on ISBT 128 implementation.

In general, the attributes of ISBT 128 include an enhanced unique donor identification system; an improved data structure for critical information (e.g., blood group, expiration date); an internationally recognized product description database; an eye-readable, machine-readable uniform labeling format; and a more accurate, flexible bar coding system.[187] In addition, unlike ABC Codabar, ISBT 128 supports concatenation, which is the ability to integrate data from paired bar codes into a single data message.[184] Furthermore, ISBT 128 contains check characters to further reduce scanning errors.[184] A sample ISBT 128 label is shown in Figure 12–1, which illustrates the standardized four-quadrant layout and the key label features of the ISBT 128 system.

Located in the upper left-hand corner is the unique donor identification code, which is a 13-character data set composed

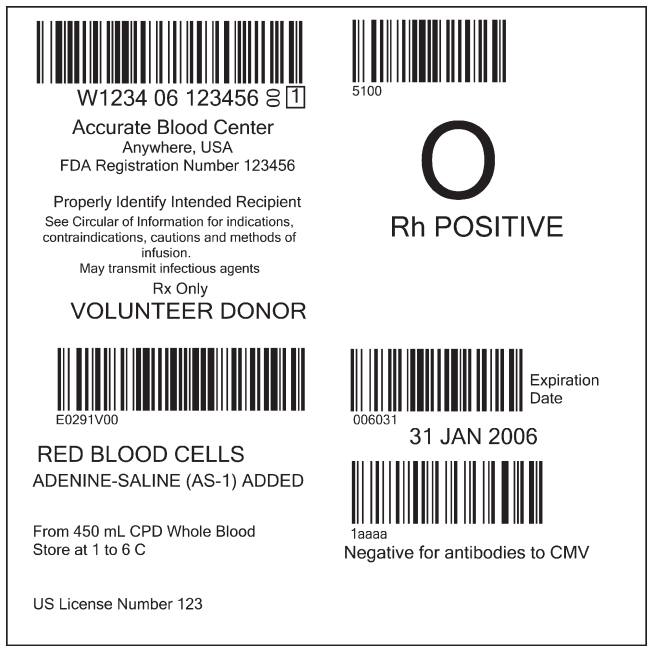

Figure 12–1 Sample ISBT 128 Label. (Used with permission of ICCBBA, Inc.)

of the collection facility identifier, the collection year, and a 6-digit donation sequence number. Adjacent to the unique donor identification code is an enclosed checksum digit to ensure accurate data entry if the number is entered manually by keyboard. Compared to the 7-digit donor identification number used by ABC Codabar that results in duplicate donor numbers, the ISBT 128 13-digit code provides more than sufficient characters to give each donation a unique identifier. The upper right-hand corner contains the ABO/Rh designation, which was previously required to be of a designated color. To accommodate the use of black-and-white, on-demand, in-house label printing, the FDA has proposed a regulatory change to the CFR that will allow for an alternative black-and-white color scheme with optional use of the traditional multicolor scheme.[188] The lower right-hand corner contains the section for product expiration and, if applicable, a space for a special testing label, such as for CMV-negative products. The lower left-hand quadrant contains the alphanumeric product code (up to eight characters), which includes information on the component class (e.g., red blood cells), modifier (e.g., washed), core conditions (anticoagulant, volume, and storage), attributes (e.g., irradiated), and intended use of the product. Currently, with all combinations of the component class, modifiers, and attributes, the ISBT 128 Product Code Database contains more than 5000 blood product codes that provide unique, specific product identification.

AABB has published the "ISBT Code 128 Implementation Plan," which provides specific information for the transition to ISBT 128 and a time line for implementation. ISBT 128 is not in the public domain, and all blood manufacturing facilities that plan to implement ISBT 128 must register with ICCBBA and pay an annual licensing fee based on the facility's annual product collections. For transfusion services that do not manufacture blood products, registration with ICCBBA is optional. In addition, at the time of this writing, the establishment must notify the FDA prior to conversion to ISBT 128.

A recent survey by AABB of blood facilities that have implemented ISBT 128 indicates that the typical time for complete implementation is less than 6 months. The most common logistic challenges encountered by the surveyed facilities were achieving compatibility between the new computer software and hardware and issues with label scanning, reading, and printing. Additional obstacles that were cited included coordination with facility customers and suppliers, validation of ISBT 128, and managing staffing for ISBT 128–associated activities while maintaining operations.[186]

SHIPPING

Shipping and receiving diagnostic specimens and blood products is an essential part of the blood manufacturing process. Regulations for the interstate transport of biological materials are established by the Department of Transportation (DOT) for ground transport, the International Air Transport Association (IATA) for air transport, and the United States Postal Service (USPS) for mail transport. Diagnostic specimens and components that have a high likelihood of containing an infectious agent must be packaged in compliance with 42 CFR 72 and shipped in accordance to the requirements set forth by the IATA, USPS, and the Centers for Disease Control and Prevention (CDC).[189] In general, the shipping requirements for clinical specimens and infectious materials include proper labeling formats to ensure clear recognition of the biohazardous contents and required packaging, such as use of leak-proof containers, shock-absorbent material, and liquid-absorbent material to reduce the risk of breakage and leakage of the transported contents. For diagnostic specimens, if damage or leakage does occur, only the shipper and receiver are to be notified. However, for infectious substances, if breakage or leakage occurs, the package must be appropriately isolated, and the CDC must be immediately notified by the contact information present on the required "Infectious Substance" shipping label.[189]

Blood products that have tested negative for infectious disease markers, or that are untested but have been obtained from screened, healthy donors, are not considered to be infectious; thus, they are not subject to all of the shipping requirements for diagnostic specimens or infectious materials. Blood products are required to be inspected for defects or abnormal appearance immediately prior to packaging and on receipt. In addition, for transport, a packaging system that protects the contents from damage and maintains the appropriate temperature range is necessary to ensure the safety and quality of the product.

With refrigerated whole blood and red blood cells, the required transport temperature range is 1 °C to 10 °C. To maintain this range, units are surrounded by bags of wet ice and encased in polyurethane insulation within a corrugated cardboard shipping container. On delivery, a procedure to confirm that the temperature remained within range during transport must be performed using one of the following methods: measurement with a thermometer at the time of delivery, use of a specialized "high-low" thermometer in the shipping container, or visual inspection of an "out-of-range" temperature indicator in the shipping container. For platelets, a room temperature platelet shipping system composed of a durable, insulated polyurethane container with gel-based temperature stabilizing (phase change) packs has been shown to maintain platelet temperature from 20 °C to 24 °C during transport, even in extreme conditions (−10 °C).[190] For frozen plasma products and RBCs, an insulated packaging system that uses dry ice is employed to maintain products in the frozen state during transport. Dry ice is considered a hazardous material, and its use requires special training, handling, packaging, and shipping procedures. Because dry ice can result in burns and asphyxiation if mishandled or improperly stored, individuals who handle or transport material containing dry ice must receive HAZMAT instruction on the use of personal protective equipment, effective packing and ventilation, and proper storage and disposal.

Chapter 13

Red Blood Cell Metabolism during Storage: Basic Principles and Practical Aspects

John R. Hess • Ginine M. Beyer

INTRODUCTION

The mature human red blood cell (RBC), lacking nucleus and mitochondria, is released into the vascular space with a protein content that is 97% hemoglobin. Over its approximately 120-day life span, the RBC circulates, carrying oxygen nested in hemoglobin molecules and deriving nutrients from and excreting waste into the plasma. The demise of this apparently simple and monofunctional cell was historically assumed to be due to the slow breakdown of its metabolic machinery.

The RBC is now recognized to be more than just "a hapless sack of hemoglobin."[1] RBCs have a focused and sophisticated metabolism that supports biophysical responses to environmental changes and allows programmed cell death. RBC metabolism includes the glycolytic pathways producing both energy (as adenosine 5′- triphosphate, or *ATP*) and oxidation-reduction intermediates that support oxygen transport and membrane flexibility.[2] RBCs interact with their environment by changing shape in response to pH and by secreting ATP in response to sheer forces and nitric oxide in response to hypoxia.[3–5] At the end of their life span, RBCs undergo programmed cell death in two ways: by racemization of negatively charged membrane phospholipids in response to calcium or low concentrations of ATP, and by the active loss of membrane through microvesiculation.[6] Increasing knowledge of RBC metabolism and homeostasis has led to better understanding of the so-called red cell "storage lesion" and to improved methods of preserving viable RBCs for transfusion and as blood bank reagents.

The *storage lesion* is a blanket term used to encompass all of the "bad" things that happen to RBCs during storage.[7] These "bad" things include: decreased concentrations of ATP and 2,3-diphosphoglycerate (2,3-DPG), increased concentrations of extracellular potassium, changes in cell shape, loss of RBC viability, and hemolysis. Although elevated extracellular potassium concentrations in stored RBC units are not usually of clinical significance, they can, however, be fatal if RBC concentrates are infused in large volumes through central vascular catheters, as in neonatal exchange transfusions or when priming cardiopulmonary bypass machines.[8] Hemolysis results not only in a reduction of the relative number of stored RBCs that survive when returned to circulation, but also in the release of harmful breakdown products. Free hemoglobin causes vasoconstriction, endothelial cell activation, and renal tubular damage.[9] Free membrane phospholipids are procoagulant. The clinical consequences of the early forms of RBC shape change or reduced 2,3-DPG concentrations are much less clear. The loss of viability during storage reduces the effective transfused RBC dose, but the consequences of administering intact but nonviable cells are not known.[7]

The evolution of RBC storage solutions and storage systems has been driven historically by military need and funding for durable blood products, rather than by academic interests.[10,11] However, the addition of phosphate and adenine to blood storage solutions followed the recognition of the roles these compounds play in normal RBC metabolism.[12] The development of plastic bags and separate RBC additive solutions was a response to the need for sterile blood plasma for fractionation.[13] Leukoreduction of blood components was first undertaken as a safety measure, and only secondarily recognized to improve the quality of stored RBCs. Unfortunately, regulatory controversy and clinical inertia slowed the inclusion of these technical advances into routine clinical practice to about one per decade. In the past 10 years, however, the basic sciences of red cell metabolism and physiology have broken important new ground. These discoveries provide a basis for future advances in blood storage and product use that is at once broad, fertile, and reliable.

RBC METABOLIC PATHWAYS

RBCs use energy to pump ions and phospholipids, limit the effects of oxidation, and shed membrane.[14] RBC function depends on ion pumping and maintaining phospholipid asymmetry. If the cells do not pump out calcium and move the negatively charged phospholipid phosphatidylserine to the inner surface of their membrane, they are rapidly removed from circulation. The binding of oxygen to hemoglobin is not perfectly reversible.[15] In about 1% of binding events, the oxygen takes an electron from the hemoglobin iron, thus forming superoxide and methemoglobin. Methemoglobin is unstable and will not bind oxygen.[16] Without a methemoglobin reductase system, RBCs would function for only a few hours.[17] Some of the superoxide formed in hemoglobin oxidation goes on to damage membrane lipids.[18] RBCs have a mechanism to concentrate these damaged lipids and shed them in membrane microvesicles.[19]

RBC energy metabolism, in turn, uses four major biochemical pathways.[2] The Embden-Meyerhof glycolytic pathway allows glucose to be broken down to two molecules of lactate, with the net production of two molecules of ATP and two molecules of reduced nicotinamide-adenine dinucleotide (NADH). This pathway is the major source of biochemical energy for cellular processes and of reducing equivalents for methemoglobin reduction. The Rapoport-Leubering shunt diverts 1,3-diphosphoglycerate from the mainstream of glycolysis to allow the production of 2,3-DPG in a pH-regulated manner.[20] The hexose monophosphate shunt is an alternative pathway of glycolysis that produces reduced nicotinamide-adenine dinucleotide phosphate (NADPH) for glutathione reduction. This shunt can also accept ribose phosphate from inosine breakdown as an alternative energy source. Purine metabolic pathways provide adenine monophosphate (AMP) and adenine diphosphate (ADP) as substrates for ATP production. Enzymes involved in these energy pathways represent about 10% of the more than 300 proteins found in RBCs.

Embden-Meyerhof Pathway

Figure 13–1 shows the Embden-Meyerhof glycolytic pathway with the associated Rapoport-Leubering shunt.[2,21] In the first three steps of the glycolytic pathway, glucose is phosphorylated to glucose-6-phosphate, isomerized to fructose-6-phosphate, and phosphorylated again to fructose-1,6-diphosphate. Both the first and third steps require a molecule of ATP. Even in the presence of glucose, glycolysis stops if ATP is depleted. In the fourth step, the six carbon sugar fructose-1,6-diphosphate is broken down into two phosphorylated molecules of three carbons each. One of those molecules is glyceraldehyde-3-phosphate, and the other is dihydroxyacetone phosphate, which is then isomerized to glyceraldehyde-3-phosphate, as well. In the fifth step, the glyceraldehyde-3-phosphate is phosphorylated again to 1,3-diphosphoglycerate, with the energy provided by its dehydrogenation and with the simultaneous reduction of a molecule of NAD to NADH. In the final five steps of the pathway, 1,3-diphosphoglycerate gives up a phosphate to make a molecule of ATP and form 3-phosphoglyceric acid; 3-phosphoglyceric acid is mutated to 2-phosphoglyceric acid, which in turn is isomerized to phospho(enol)pyruvate; phospho(enol)pyruvate transfers its phosphate to ADP to make ATP and pyruvate; and pyruvate is oxidized to lactate, again reducing NAD to NADH. The result of this pathway is that one molecule of glucose is broken down to two molecules of lactate anion and two protons, with the net production of two molecules of ATP and two molecules of NADH.

The rates of glycolysis in the Embden-Meyerhof pathway are directly controlled by the availability of the substrates for its initial reactions, glucose and ATP, and by pH and PO_2.[22] Glucose can be replaced by fructose, both of which pass freely into human RBCs through a specific hexose transporter.[23] However, the initial energy-requiring steps of the pathway cannot be bypassed by providing the phosphorylated forms of the sugars, because these are not transported across the RBC membrane. As decreasing pH reduces the rate of glycolysis, a point is reached where ATP production does not keep up with ATP use. If glucose is removed and the RBC ATP concentrations are allowed to decrease, a point is reached where adding glucose back only rescues a fraction of the cells.

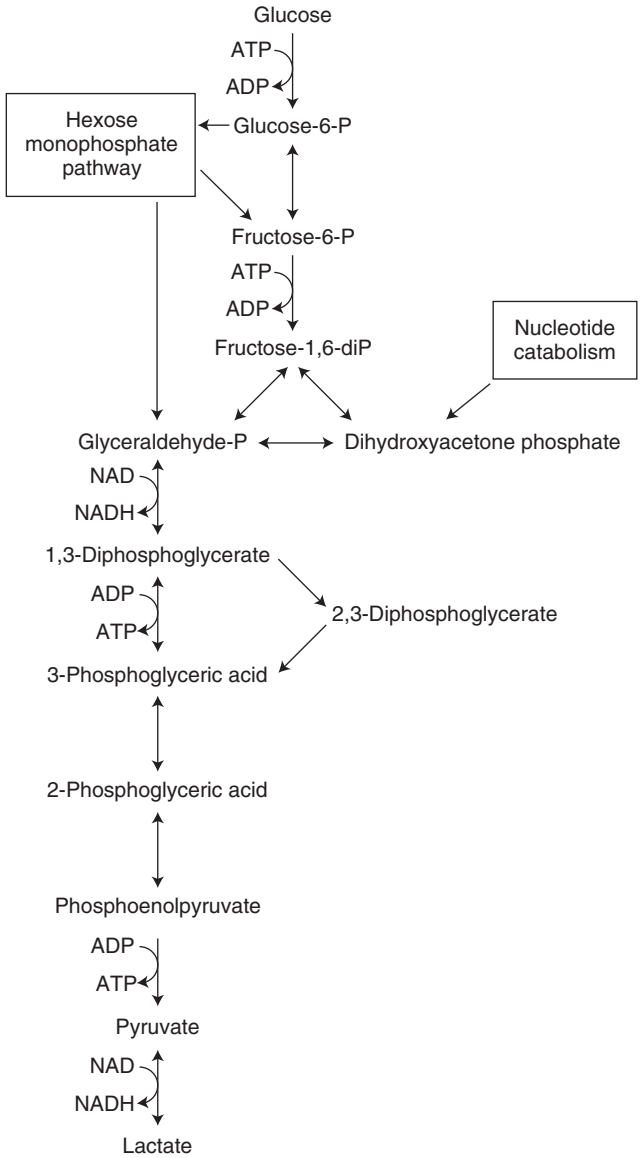

Figure 13–1 The Embden-Meyerhof glycolytic pathway along with the associated Rapoport-Leubering shunt. (From Beutler E. Red cell metabolism and storage. In Anderson KC, Ness PM, [eds]: Scientific Basis of Transfusion Medicine: Implications for Clinical Practice. Philadelphia, WB Saunders, 1994, pp 188–202.)

Rapoport-Leubering and Hexose Monophosphate Shunts

The Rapoport-Leubering shunt, also shown in Figure 13–1, allows 1,3-diphosphoglycerate to be mutated into 2,3-DPG. At an intracellular pH greater than 7.2, large amounts of 2,3-DPG are produced.[20] In the cell, 2,3-DPG serves as a steric effector of hemoglobin, stabilizing deoxyhemoglobin and thereby shifting the hemoglobin oxygen equilibrium curve to the right (reducing oxygen affinity). 2,3-DPG is broken down by phosphatase activity to 3-phosphoglyceric acid. The Rapoport-Leubering shunt thus makes 2,3-DPG at the expense of bypassing the ATP-making step in glycolysis from 1,3-diphosphoglycerate to 3-phosphoglyceric acid. If all of the three-carbon glycerate phosphates made from glucose went through the Rapoport-Leubering shunt, there would be no net ATP production from glycolysis.

The hexose monophosphate or pentose shunt also branches from and feeds back into the Embden-Meyerhof

pathway, again shown as a block in Figure 13–1. In the first three steps, glucose-6-phosphate is dehydrogenated twice, making two molecules of NADPH for glutathione synthesis and reduction, at the cost of a carbon lost as CO_2, and leaving a pentose phosphate. In the remainder of the pathway, the pentose phosphates are variously isomerized, and pairs of them are mutated into 4- and 6- and 3- and 7-carbon phosphated sugars. The 3- and 6-carbon phosphated sugars, glyceraldehyde-3-phosphate and fructose-6-phosphate, respectively, can return to the Embden-Meyerhof pathway. Moreover, the pentose phosphate pool can be fed with ribose-1-phosphate from the breakdown of inosine monophosphate (IMP), providing a pathway for the manufacture of ATP and NADH in the distal Embden-Meyerhof pathway that is independent of both glucose and initial stores of ATP. The flux of sugars through the upper end of the hexose monophosphate shunt is regulated by the availability of NADP (i.e., the level of redox stress on the RBC) and the lower half by the availability of pentose phosphates.

RBC Nucleotide Metabolism

Nucleotide metabolism is necessary to maintain substrates that support the formation of the high-energy intermediate ATP and guanosine triphosphate (GTP). In the RBC, adenine and phosphoribosylpyrophosphate are converted to AMP, and adenosine can be activated to AMP by ATP. AMP, in turn, can also be activated to ADP by ATP. ATP is made from ADP and phosphate by specific enzymes in the lower limb of the Embden-Meyerhof pathway. ATP and AMP can also be made from two ADP, because the ADP activating reaction is reversible. AMP is slowly and irreversibly deaminated to form IMP, which is further broken down to hypoxanthine and pentose phosphate.

A similar set of enzymes supports the maintenance of GTP. GTP does not appear to have a role as an energy intermediate in RBCs, but instead it serves as a concentration-dependent inhibitor of the enzyme transglutaminase that crosslinks proteins in a primitive coagulation process.[24] Thus, maintaining normal concentrations of GTP appears to be necessary to prevent transglutaminase from randomly cross-linking RBC proteins, thereby damaging protein function and membrane flexibility.

THE STORAGE LESION

When RBCs are stored in liquid suspension in the cold, metabolism slows, metabolic byproducts and cellular breakdown products accumulate in the suspending fluid in the closed container, and the RBCs change shape, lose viability, and finally rupture.[7] The slowing of metabolism is the desired result of cooling, in that it allows RBCs to be stored for longer periods than is possible at room or body temperature. However, during storage, potassium and hemoglobin increase in concentration in the suspending plasma, and the pH falls. At the same time, the cells develop bumps, followed by spicules from which microvesicles bleb, and the cells finally fall apart. Overall, a decreasing fraction of RBCs survives after being returned to the circulation. These changes are collectively known as the *storage lesion*.

RBC glycolysis slows threefold for each 10°C decrease in temperature.[25] Thus, a conventional unit of RBCs can be stored about a day at 37°C, 3 to 4 days at room temperature, and 5 to 6 weeks at 1°C to 6°C. With each of those times and temperatures, sufficient glucose is metabolized to produce enough protons to reduce the pH to the point where further metabolism is inhibited; ATP concentrations then fall to levels that do not support cell viability.

However, the thermal coefficients of all of the individual enzymes and pumps in the RBC are not the same. This is most readily seen for the Na-K ATPase that pumps potassium into, and sodium out of, the RBC. At 4°C, the pump's activity is well below the small ion conductance of the membrane, leading to a decrease in cytosolic potassium concentration and a corresponding increase in extracellular potassium of about 1 mEq/L/day. The resulting high suspending fluid potassium concentrations are occasionally clinically important, causing arrhythmias when old RBC concentrates are infused at high volume into the central circulation, but the ion loss does not seem to have any direct effect on RBC viability.

The decreasing pH of metabolically active stored RBC inhibits the production of 2,3-DPG. Normal venous blood typically has a pH of about 7.35. When acidic storage solutions are added, the pH is reduced to below 7.2, and the Rapoport-Leubering shunt is largely bypassed during glycolysis. The concentrations of 2,3-DPG then fall over the first 10 days of storage.

During storage, RBCs change shape.[26] The biconcave disks first develop a knobbled appearance, which progresses into blunt echinocytic projections, and then into sharp spicules from which microvesicles are shed. The early stages in this process are reversible with warming, but the shedding of membrane cannot be undone. Membrane loss makes RBCs smaller and more rigid as they become spherical and finally rupture. The shape change progression can be measured by RBC morphology scoring systems, whereas the loss of membrane is seen as increasing osmotic fragility or shed microvesicle mass. However, the relationship between RBC membrane loss and reduced cell viability when returned to the circulation is not known.

The functional viability of RBCs during storage is measured by their ability to persist when returned to the circulation. Differential agglutination, radioactive labeling, and biotin labeling with flow cytometry have all been used to measure the persisting infused cell fraction. Most recent experience has depended on chromium-51 labeling of stored RBCs, and standard methods for the measurement have been published.[27] In most such studies, stored RBCs are labeled and returned to the circulation of the donor who initially provided them. Performed correctly, this practice prevents the transmission of disease to study subjects and avoids alloimmune removal of the cells that would invalidate the measurements.

A portion of the infused labeled and stored RBCs is cleared rapidly from the circulation, so the standard measurement for comparing storage systems is the fraction of infused cells that remains in the circulation 24 hours after infusion. Determining this fraction from the concentration of cells circulating at 24 hours requires a reasonable estimate of the number of cells circulating immediately after infusion. This number can be determined by statistical regression of a series of early measures made between 5 and 15 minutes after infusion back to the time of infusion, or by labeling fresh cells with a second isotope, such as technicium-99m, to obtain an independent measure of the whole body RBC volume. When the fraction of infused stored RBCs surviving for 24 hours (the *recovery*) is greater

than 80%, the rapidly cleared fraction tends to be small, and the two estimates are usually close. Double-label recovery measures are useful for understanding poor recovery, but single-label measures are often sufficient when recoveries are high. Fifty years of storage studies using chromium-51 recovery measures have consistently shown that RBCs that persist in the circulation for 24 hours survive normally and have a 50-day half-life.

An important insight into the meaning of the early loss of RBCs in recovery measurements comes from work by Hogman and his colleagues in a study of the effect of metabolic rejuvenation.[28] RBCs stored for 6 weeks had a mean recovery of 77%. When RBCs from the same units were metabolically rejuvenated by warming and replenishing glycolytic intermediates with pyruvate, adenine, inosine, and phosphate for two hours, the recovery rose to 89%. Thus, more than half of the stored RBCs removed from the circulation in the first 24 hours were not dead.

It is now clear that stored RBCs do not just run out of metabolic energy. Rather, they are undergoing a program of cell death.[29] The program includes the racemization of negatively charged membrane phospholipids and the loss of membrane by microvesiculation. These activities are also components of the apoptotic process in nucleated cells. Both of these processes are inhibited by normal concentrations of ATP in RBCs, and the racemization of phospholipids is reversible with the restoration of ATP concentrations in the metabolic rejuvenation process just described. The relative contributions of senescent RBC death and programmed RBC death can be estimated in the ratio of microvesicular hemoglobin to free hemoglobin in the suspending fluid of stored RBCs.

RBC STORAGE IN LIQUID MEDIA

History

Lee described the use of citrate as an anticoagulant for human blood in 1913, and Rous and Turner showed that glucose delayed the hemolysis of RBC suspended in saline in 1915.[30] Rous and Turner went on to make the first RBC storage solution of citrate and glucose and showed that rabbit RBCs could be stored for 4 weeks with minimal hemolysis.[31] When the stored RBCs were returned to the rabbit donors, the hematocrit increased without significant bilirubinuria.[32] Robertson, who worked with Lee at Harvard and then with Rous and Turner at the Rockefeller, used their storage solution to collect group O whole blood in bottles and then demonstrated the utility of this stored blood as a resuscitation fluid on the battlefields of France in World War I.[33] Mollison has eloquently described the importance of the combination of citrate and glucose, saying that citrate allows the donor and the recipient to be separated in space, whereas glucose allows them to be separated in time. These and more sophisticated storage solutions are the basis for modern RBC banking.[34]

A problem with the original Rous-Turner solution was that the RBCs were stored in very dilute suspensions, 70% solution to 30% blood for a storage hematocrit of about 12%. In the late 1930s, DeGowin reformulated the solution for 60:40 mixtures, and in the early 1940s, Alsever again modified the solutions for 50:50 ratios.[35,36] However, the major advance during World War II was Loutit and Mollison's acid citrate dextrose (ACD) solution, designed for use in a 1:4 ratio and later concentrated further for 1:7 mixing with whole blood.[37] Acidifying the solution to pH 5.5 allowed the citrate and glucose to be autoclaved together without caramelizing the sugar, so that blood collection sets could be manufactured and distributed with sterile vacuum bottles containing premixed anticoagulant. Concentrated whole blood, and later, packed RBCs, made resuscitation faster. Sterile ACD allowed RBCs to be stored with minimal hemolysis for 3 weeks.

In addition to reduced bacterial contamination, the new ACD solution improved in vivo RBC recovery despite the acid pH. It took a decade to determine that ACD solution had little buffer capacity, so that its acidity did not much reduce the initial pH of stored blood. At the same time, the lower volume of anticoagulant solution added to whole blood reduced the amount of phosphate that diffused from stored RBCs, leaving more intracellular phosphate as a substrate for ATP production.[38] This realization led to the addition of phosphate to ACD to make citrate phosphate dextrose (CPD) solution. The added phosphate did increase the anticoagulant solution buffer capacity, but the resulting lower initial pH of the stored blood was less important than the provision of the metabolic substrate. CPD was better than ACD in clinical testing, providing higher in vivo recoveries and reduced hemolysis. Based on these results, CPD was considered but never approved for 4-week storage of whole blood.

Subsequent advancements in RBC storage include plastic bags in the 1960s, adenine to make citrate phosphate dextrose adenine (CPDA-1) for 5-week RBC storage in the 1970s, separate RBC additive solutions for 6-week storage in the 1980s, and leukoreduction in the 1990s.[39] This slow developmental cycle meant that CPDA-1, a solution designed for whole blood storage, was finally licensed eleven years later in the era of blood components. However, when plasma was removed to make component plasma products and platelets, the in vivo recovery of the stored packed RBCs decreased due to insufficient glucose.[40,41] Additive solutions were developed to replace the volume and nutrients removed with plasma, resulting in RBC survival that was as good or better than in native plasma. Current leukoreduced RBC concentrates in additive solution can be stored for 6 weeks with an 82% mean recovery and about 0.4% hemolysis. Leukocyte reduction, by removing highly metabolically active cells that will decrease the pH of the storage solution, and by removing sources of proteases and phospholipases that damage RBCs, generally improves the measured recovery of current 6-week stored RBC by about 4%.

Current Liquid RBC Storage Systems

Two types of liquid RBC storage systems, combined anticoagulant-nutrient solutions and additive solution systems, are in general use in the United States. RBC units stored in additive solutions are much more common. CPDA-1 is the only anticoagulant and nutrient solution in regular use. To make such RBC units, whole blood is drawn directly into the solution at a 7:1 volume ratio (450 mL blood to 63 mL of CPDA-1) and the plasma separated to leave an RBC concentrate with a storage hematocrit of about 75%. Such units are licensed for 5-week storage, and the in vivo RBC recovery at the end of 5 weeks of storage is approximately 75%. With additive solution systems, whole blood is first drawn into a CPD-like solution, again at a 7:1 volume ratio. Plasma is then removed for component manufacture, and 100 mL to 110 mL of additive solution is added. RBCs in additive

solutions typically have a lower storage hematocrit, 55% to 60%, and a higher in vivo recovery, averaging 78% to 84% after 6 weeks of storage.

For many years, the two kinds of stored RBCs have been maintained side-by-side in blood banks because pediatricians did not want small children exposed to the mannitol or extra citrate in the commercially available additive solutions, and trauma surgeons complained that the concentrated RBCs in CPDA-1 flowed too slowly for effective resuscitation of the injured.[42,43] Now that infants have been shown to tolerate infusions of 15 mL/kg of RBCs in the common additive solutions, collection of RBCs into CPDA-1 is decreasing.[44,45]

The additive solutions (AS) used in North America, AS-1, AS-3, and AS-5, appear to store RBCs equally well. Theoretical reasons to prefer one solution over another do not appear to correlate with clinical differences. However, the additive solutions work in slightly different ways. AS-1 and AS-5 contain saline, adenine, glucose, and mannitol. The added adenine replaces RBC adenine lost to adenine deaminase, and the mannitol suppresses membrane loss, probably by a combination of direct physical interactions and by trapping oxygen free radicals. AS-3 contains saline, adenine, glucose, phosphate, and citrate. The citrate, another sugar, serves as a membrane protectant in a manner similar to that of mannitol. Citrate has the advantage that it is readily metabolized when infused and the disadvantage that it can contribute, although minimally, to citrate toxicity. The phosphate serves to maintain intracellular phosphate concentrations, a function that can be important if RBC units are underdrawn or drawn from anemic individuals. Under these conditions, the volume ratio of AS to RBCs can be high, and intracellular phosphate can be lost.

In Europe, a single additive solution, saline adenine glucose mannitol (SAG-M), has been standard for several decades. Although SAG-M has the same ingredients and essentially the same composition as the AS-1 and AS-5 solutions used in the United States for 6-week storage, it is usually used for 5-week RBC storage.

Two other, newer additive solutions are available with 7-week storage times. Walker developed an additive solution of phosphate, adenine, glucose, guanine, saline, and mannitol (PAGGS-M).[46] Its development followed the long tradition of searching for extra nutrients that might extend RBC storage. The phosphate prevents stored RBCs from becoming phosphate depleted from slow diffusional loss across a concentration gradient from inside to outside of the cells. Guanine was added to support GTP concentrations before it was understood that low GTP concentrations are rare in stored RBCs. The solution was licensed for 7-week storage in 1993, when the German government wanted a long-term RBC storage solution to support its United Nations peacekeeping mission in Somalia.[47] The studies that were submitted for licensure showed 74.7% in vivo recovery, a value that would not pass the U.S. standard of 75%.

A second system for 7-week storage, 1/2CPD-ErythroSol (Baxter), was designed to maintain pH at a higher level longer.[48] In this system, one half the normal volume of acid CPD is used in the collection phase, to blunt the decrease in pH associated with mixing venous blood with citric acid and monosodium phosphate. The additive solution portion of the storage system contains sodium chloride, adenine, glucose, mannitol, and phosphate at pH 7.5, which is achieved by mixing monosodium and disodium phosphate and made autoclavable by storing the sugar and phosphate in different pouches. The combined additive solution components have a final volume of 150 mL. The system allowed in vivo RBC recoveries of 78% at 7 weeks, but there were occasional problems with coagulation during whole blood collection because of the reduced amounts of primary CPD anticoagulant. The increased additive solution volume led to a reduced storage hematocrit of about 50%, which might cause problems with excessive hemodilution in massive transfusion situations.

Currently available liquid RBC storage systems work well in urban clinical medicine. Liquid RBC concentrates are easy to manufacture and handle, and the cells are accordingly safe, available, effective, and inexpensive. RBCs last long enough that almost 95% of all RBC components are transfused, and the majority of recipients receive cells that are only a few weeks old. Such cells are expected to have excellent in vivo recovery and little loss of membrane. However, at the end of the supply lines in small, rural hospitals and remote overseas territories and military bases, the average age of blood increases while the efficiency of use goes down. The use rate for RBCs sent to the peacekeeping forces in Bosnia from 1995 to 2000 was 1.7%, and for troops in Iraq and Afghanistan from 2002 to 2004 it was 2%. Moreover, in some retrospective studies the use of older cells has been associated with increased multiple organ failure and death.[49] Thus, the military wants a longer shelf-life for liquid-stored RBCs, and there is a perception that generally better storage is needed, as well.

Designing Better RBC Storage Systems

In 1986, Meryman and his colleagues described storing RBCs for 14 weeks in an ammonia-containing liquid storage solution at 1° C to 6° C, with occasionally excellent in vivo recovery.[50] They went on in 1994 to show that RBCs could be stored in very dilute suspensions for 35 weeks.[51] Such demonstrations show that the 5- to 7-week limits of conventional liquid RBC storage are not a result of anything intrinsic to the RBCs themselves but are a consequence of currently employed methods.

The Meryman solution appeared to work by maintaining very high concentrations of RBC ATP, presumably because ammonium prevented feedback inhibition of glucose phosphorylation.[52–55] Because ammonia would need to be washed out of the RBC component before it could be transfused, this storage solution was not compatible with routine clinical use. However, the idea that maintaining high concentrations of RBC ATP improved storage was compatible with the observation that the RBC ATP concentration was the laboratory measure that best correlated with the in vivo recovery of stored cells.

In 1992, Greenwalt and his colleagues described 9-week storage of RBC in a dilute, alkaline, ammonia- and phosphate-containing solution.[56] Again, ammonia made the solution unsuitable for clinical use, but it also appeared to work by maintaining high concentrations of ATP in the RBCs. However, careful review of several of Greenwalt's prior studies raised the possibility that it was the alkaline phosphate and not the ammonia that was driving the increase in ATP.[57,58] Hess and his colleagues then showed that the addition of disodium phosphate to conventional saline, adenine, glucose, and mannitol created a simple additive solution that increased RBC ATP concentrations and reduced hemolysis with increasing dose.[59] A 200-mL version of this

experimental additive solution (EAS) allowed RBCs to be stored for 9 weeks, with 77 ± 7% in vivo recovery and 0.35% hemolysis.[60] A 300-mL version, EAS-64, allowed RBCs to be stored for 10 weeks, with 84 ± 8% in vivo recovery and 0.43% hemolysis.[61] Moreover, the loss of membrane through microvesiculation was one fifth that of control RBCs stored for 6 weeks in AS-1.

The combined groups of Greenwalt and Hess then tested the roles of pH and tonicity; the concentrations of phosphate, mannitol, and sodium; and the effect of plastic bags on these storage systems.[62–65] They showed that pH had to be maintained between 7.2 and 6.4. Above pH 7.2, 2,3-DPG was made at the expense of ATP, and the cells did not recover. Below pH 6.4, glycolysis essentially stopped. Phosphate in the extracellular fluid prevented the net loss of the intracellular phosphate necessary for ATP production. Phosphate also served as a pH buffer, but there were clinical limits on its safe concentration. Mannitol inhibited hemolysis, but most of the benefit was seen below 30-mM concentrations. Low sodium concentrations reducing tonicity to 290 mOsm resulted in cell swelling and reduced hemolysis. Storage in polyvinyl chloride (PVC) bags plasticized with diethylhexyl phthalate (DEHP) reduced hemolysis fourfold compared to storage in polyolefin bags.

This same series of studies examined the flow of metabolic energy through RBC storage systems. In 5-week CPDA-1, a unit of RBCs consumed 3 mM of glucose, produced 6 mM of lactate and protons, and dropped the pH from 7.0 to 6.5.[25] The proton buffering capacity of the system came almost entirely from the lysines on hemoglobin in the RBC. Lactate production was twice as fast in the first week as in the last. ATP production was maintained only above pH 6.7. During 10 weeks of storage in EAS-64, the pH decreased from 7.25 to 6.5, buffering 9 mM of protons with hemoglobin and 1 mM with phosphate. The additional storage time and membrane quality was bought with greater energy use. Better RBC storage required more proton buffering capacity, which could only be obtained by increasing the volume of the storage solutions or increasing their intrinsic buffering capacity. Clinical considerations suggested that patients would not tolerate the additional volume.

Buffering RBC storage was originally proposed and developed by Beutler in a solution called BAGPM (bicarbonate, adenine, glucose, phosphate, and mannitol).[66] When the bicarbonate picks up a proton, carbonic anhydrase converts the resulting carbonic acid to water and CO_2, the CO_2 diffuses out through the plastic bag, and the system effectively loses a proton. Unfortunately, Beutler added so much bicarbonate to BAGPM that he increased its pH to 7.8, reduced ATP concentrations in the stored blood, and observed poor in vivo recoveries. The Greenwalt and Hess groups used lower concentrations of bicarbonate and balanced the solutions to have a maximum pH of 7.2 at the beginning of storage. With bicarbonate, the groups made EAS that allowed 11 to 12 weeks of storage in 300-mL versions and a candidate 100-mL solution that stored RBC with 87 ± 2% in vivo recovery after 8 weeks, with reduced hemolysis and membrane loss. It is likely that such solutions can be improved further.[67–69]

Thus, it is possible to make better RBC storage systems by changing additive solutions to maintain ATP concentrations in the physiologic range. This goal can be accomplished by optimizing pH, buffering the solutions with bicarbonate and phosphate, using membrane protectants such as mannitol, and reducing sodium and chloride content. Solutions made using this general plan can store RBCs longer and with less membrane loss. The best balance between length of storage and membrane loss is not known at this time.

The best approach to integrate these advances into practice is still unclear. Current liquid storage systems appear to maintain RBCs with very little loss of membrane or viability for several weeks, followed by a phase marked by decreasing recovery and increasing stiffness. The regulatory standard of 75% in vivo recovery is a compromise between what had been achieved with storage system development in the past and what is compatible with meeting the demands of a national blood system. Shorter time limits on RBC storage will improve quality. Longer storage improves logistic efficiency at a time when blood availability is a serious problem. The new storage technology appears good enough that simultaneous improvement in RBC quality and shelf-life are possible.

Chapter 14

Infectious Disease Testing: Basic Principles and Practical Aspects

Roger Y. Dodd

BRIEF HISTORICAL REVIEW

The risk of disease transmission by blood transfusion is extremely low, particularly in developed nations. This situation is a consequence of a number of interlocking safety measures, including the selection of safe populations from which donors are drawn, careful donor questioning, laboratory testing, record keeping, and the use of quality systems and good manufacturing practices. These approaches have evolved over the years, and perhaps the most change has been seen in the area of blood testing. Indeed, blood collectors have now added nucleic acid amplification techniques to the battery of tests directed toward the safety of the blood supply. However, although transmission of known agents has almost been eliminated, residual fear of the unknown, fueled by a continuing stream of newly emerging or newly recognized microbes, continues.

Although some form of blood transfusion has been used for well over a century, organized testing approaches did not really commence until the 1940s. At that time, the transmissibility of syphilis by this route was recognized, and testing (albeit using nonspecific methods) was implemented. However, viral hepatitis was the biggest unresolved concern from the 1940s to about 1970. Clinical hepatitis was recognized as an almost inevitable consequence of transfusion, but little could be done to prevent it. The greatest benefits during that time were derived from epidemiologic studies that established the increased infection risk attributable to commercial donors and prisoners. There were also a number of attempts to use liver function tests to screen blood donors for risk of hepatitis transmission, but none of the tests was broadly adopted.

In 1965, Blumberg and colleagues[1] described the Australia antigen, mistakenly identifying it as an allotypic protein.[2] Subsequently, the antigen was recognized as a component of the hepatitis B virus (HBV), fortuitously produced in considerable excess during both acute and chronic infection. This discovery underlies the entire history of specific serologic testing for transfusion-transmissible infections. Between 1969 and 1972, all blood-collecting establishments in the United States adopted some form of testing for hepatitis B surface antigen (HBsAg), using agar gel diffusion, counterelectrophoresis, or rheophoresis. Subsequently, Ling and Overby[3] reported on a radioimmunoassay for HBsAg, and this assay was rapidly adopted. Interestingly, the insensitive gel precipitation methods seemed to affect only about 20% of post-transfusion hepatitis, and the frequency of radioimmunoassay–positive samples was about fivefold greater. A brief period of hope that the transfusion hepatitis problem was solved rapidly terminated in disillusion when it was found that most of the additional reactive results were false positive and that post-transfusion hepatitis continued to occur. As a result of the observations on specificity of the radioimmunoassay, confirmatory testing was implemented. Subsequently, testing for antibodies to the hepatitis B core antigen (anti-HBc) was licensed as a means to further reduce HBV infectivity, although it was initially introduced as a surrogate test for other forms of hepatitis. In 2004 and 2005, clinical trials of nucleic acid amplification tests (NAT) for HBV DNA were completed, and one test had been licensed as of July 2005.

Recognition of the hepatitis A virus and development of diagnostic tests for infection with this virus led to the definition of most cases of residual post-transfusion hepatitis as non-A, non-B (NANB).[4] Extensive studies were performed to characterize the agent(s) of NANB hepatitis, but such studies were without any real success until 1989.[5] Many attempts were also made to identify donor characteristics that might be used for screening. As a result of two of these studies, recommendations were made to screen donors for elevated levels of alanine aminotransferase (ALT) in the serum, and a small number of institutions adopted this measure around 1982.[6,7] Continuing studies also implicated antibodies to the hepatitis B core antigen (anti-HBc) as another surrogate for NANB infectivity.[8,9]

Further measures to reduce the incidence of post-transfusion NANB hepatitis were largely set aside as a result of the emergence of acquired immunodeficiency syndrome (AIDS) and recognition of its transmissibility by blood components and plasma fractions between 1981 and 1984. Although the potential value of the anti-HBc test as a surrogate for AIDS infectivity was discussed, this approach was adopted in only a limited number of blood establishments. Recognition of the human immunodeficiency virus (HIV) as the infectious agent of AIDS by Gallo and Montagnier and their colleagues[10,11] led to the rapid development and introduction of screening tests for antibodies to the virus. Testing started in March 1985. Because of the persistent nature of HIV infection, the presence of antibodies to HIV was closely linked to infectivity, and it is now clear that the introduction of this test played a major role in the almost total elimination of transfusion-transmitted HIV and AIDS. A problem with the exclusive use of anti-HIV as a viral marker is the fact that, early in infection, infectious virus can circulate before the appearance of detectable levels of antibody. Thus, there has been a continuing process of improvement of antibody tests and implementation of additional tests in order to reduce the

length of this infectious window period and reduce risk. Not only have antibody tests become much more sensitive, but also tests for HIV p24 antigen and now for HIV RNA have been introduced. On licensure of NAT, the p24 antigen test was shown to be superfluous and has been discontinued.

The first human retrovirus to be recognized was the human T-lymphotropic virus 1 (HTLV-1).[12] This virus is an oncovirus, and its epidemiology is characterized by extreme geographic clustering in Japan, the Caribbean, and parts of Africa. Clinical outcomes of infection with this virus are relatively uncommon but include the serious T-cell lymphoma/leukemia and a neurologic disease called HTLV-associated myelopathy, otherwise termed *tropical spastic paraparesis*. Subsequently, a closely related virus, HTLV-2, was characterized. Its epidemiology is less well defined, but it appears to be naturally endemic in certain indigenous populations in the Americas and also circulates among users of injected drugs. The first serologic tests to be developed were designed to detect antibodies to HTLV-1, but as a result of cross-reactivity, they also identified the majority of HTLV-2 infections. Epidemiologic studies in the U.S. donor population revealed a 0.025% prevalence of anti-HTLV,[13] and this figure, along with the potentially serious outcomes of infection (which had been shown to occur through transfusion), led to the implementation of donor testing in 1988.

During the same period, there was a reevaluation of the severity of long-term outcomes of NANB hepatitis. As a result of this reevaluation and of a heightened awareness of blood safety, blood establishments adopted testing for both elevated ALT levels and anti-HBc, in the expectation that these tests together might reduce the incidence of transfusion-transmitted NANB hepatitis by about 60%.[8,9] This projection turned out to be quite accurate.

However, the most important advance in management of NANB was the cloning of a portion of the genome of a virus termed *hepatitis C virus*. This advance permitted the development of a test for antibodies to the virus based on peptides expressed from the viral genome. Use of this test revealed that almost all NANB hepatitis was due to hepatitis C. The first-generation test was implemented for donor screening in 1989 and 1990. Subsequently, with the expression of additional peptides, versions 2.0 and 3.0 of the test were successively implemented, with consequent gains in sensitivity. Nevertheless, because of a significant infectious window period, NAT for HCV has also been implemented. As a result, and because none of the supposed non-A, non-B, non-C hepatitis viruses were shown to be pathogenic, testing for ALT has also been discontinued.

Unexpectedly, in 2002 it became apparent that West Nile virus (WNV), which had entered the United States for the first time in 1999, was readily transmissible by blood transfusion. Although infection with WNV is acute, the frequency of infection was so great that a significant number of blood donors did give blood in the brief viremic, asymptomatic phase. As a result of these observations, tests for WNV RNA were developed and implemented within a relatively short time (about 9 months). Well over 1000 viremic and potentially infectious donations were identified in the first 2 years of testing.[14]

APPROACH TO TESTING

In the United States, blood, blood components, and plasma products are classified as biologics. By extension, tests used in the preparation of blood are also classified as biologics and, as such, are regulated by the U.S. Food and Drug Administration (FDA). This licensure involves extensive clinical trials and stringent regulatory oversight. However, these procedures are somewhat cumbersome and involve considerable resource use by manufacturers and regulators. As a consequence, the selection of available tests in the United States may differ from that in other parts of the world. A listing of FDA-licensed tests may be found on the FDA website (http://www.fda.gov/cber/products/testkits.htm). It should be noted that some of these tests may no longer be available. Typical results from the use of these tests in a large voluntary donor population are presented in Table 14–1.

There is a broad commonality in the implementation of all tests used to ensure the safety of blood and blood components. Every donation is tested, and current requirements in the United States are that the test be performed on a sample drawn at the time of donation. With the exception of testing for viral nucleic acids, which is described later, there are three phases of the testing. Each sample is tested singly; nonreactive results are considered to be negative for the marker, and the corresponding blood unit (and its components) may be issued for transfusion. If the result is reactive, the sample is retested in duplicate. If both of the repeated test results are nonreactive, the sample is classified as negative, and the unit, or its components, is released. However, if one or both of the repeated results is reactive, the sample is classified as repeatedly reactive, and the blood unit cannot be issued for transfusion. This practice was initiated when it was recognized that radioimmunoassays (and subsequently enzyme immunoassays [EIAs]) were subject to

Table 14–1 **Prevalence and Incidence of Transfusion-Transmissible Infections among American Red Cross Blood Donors over the Two-year Period 2000–2001**

	Prevalence among First-time Donors (*n* = 3.055 million)		Incidence among Repeat Donors (4.182 million person-years)	
	Number Confirmed Positive	Rate per Hundred Thousand	Number Confirmed Positive	Rate per Hundred Thousand Person-years
HBsAg	2229	72.9	53	1.27
HCV	9420	308.3	79	1.90
HIV	313	10.2	65	1.55
HTLV	299	9.8	10	0.24

nonrepeatable reactive results related to minor contamination with the labeled conjugate.

The final phase of testing is the application of confirmatory or supplementary tests, largely intended to ensure that the donor is properly advised about the significance of the screening test results. Although imperfect, this phase of testing markedly improves the accuracy of donor notification and counseling. In certain circumstances, these additional tests may also be used to support reentry of donors whose screening test results are definitively false positive. In some countries, a second screening test is used in place of different technology. In the United States, it has proved effective to use this second EIA strategy to reduce the number of confirmatory tests that have to be performed.[15] The strategy requires that the two EIA tests have essentially the same sensitivity. Despite the use of supplementary or confirmatory testing, the general rule in the United States is that a donor is indefinitely deferred on the basis of a repeatedly reactive screening test result.

There are some exceptions to this generalized algorithm. For example, there is no supplementary or confirmatory test for antibodies to the HBc antigen. In this case, a donor is not permanently deferred until he or she is found to be repeatedly reactive on a second occasion. Recent data, however, suggest that this policy is of little value and will become even less so as the specificity of tests for anti-HBc improves. Somewhat similarly, a donor does not need to be deferred the first time a test for anti–HTLV-1 or -2 is repeatedly reactive, provided the supplementary test result is nonreactive or indeterminate.

Starting in 1999, blood collection establishments in the United States implemented NAT for HCV and HIV RNA in donor samples. This testing was performed on small (i.e., 16 or 24) pools of samples. In some cases, primary testing was performed using a multiplex system.[16] Consequently, the testing algorithms differ significantly from those outlined previously. A second round of testing is used to resolve pools, followed, in some cases, by another test to differentiate HIV from HCV. In addition, a second, different NAT procedure is used to confirm or support the results of the primary test. Initially, all NAT for donor blood in the United States was performed under Investigational New Drug (IND) protocols, but tests were licensed in 2002. Table 14–2 outlines the results of NAT for the U.S. blood donor population from March 2000 through April 2002.[16]

Infectious disease testing is not static; there is continuing improvement in four broad areas. First, individual tests are being modified to ensure improved sensitivity and specificity. This process is perhaps best exemplified by the rapid progression of anti-HCV tests from version 1.0 to version 3.0. Second, the formats of the tests and the nature of the automated instrument systems are also subject to change and improvement. In some cases, these changes improve the performance characteristics of the tests, but they also reduce the need for human intervention and improve adherence to the requirements of good manufacturing practice. Third, a better understanding of the early (window) phase of infection has led to the addition of new test methods for some agents. For example, the measures for HIV now include a test for antibodies to the virus, and a test for viral nucleic acids. In addition, a number of tests are supplemented to detect additional strains or subtypes of a given agent. Fourth, continuing concern about blood safety is likely to lead to the implementation of tests for other agents including imported diseases such as Chagas disease[17] and emerging infections such as babesiosis.

WINDOW PERIOD

At least until the late 1980s, the serologic tests in use were considered to have adequate sensitivity for detecting well-established, chronic infection. Comparison of detection rates among first-time and repeat donors generally revealed that about 50% of all confirmed positive test results were found among first-time donors, although they contributed only 20% of all donations. Concern about the continued occurrence of transfusion-transmitted HIV infection led to much closer evaluation of the risk of infectivity during the early phases of infection, particularly the viremic but antibody-negative window period. Indeed, in a study by Petersen and colleagues,[18] HIV infectivity was demonstrated in one in five seronegative donations collected from individuals who were HIV antibody positive at their next donation. Mathematic modeling showed that the period of such infectivity averaged 45 days as of 1990.[18]

Knowledge of the length of the window period and of the incidence of new infection in the donor population also permitted estimation of the residual risk of infection from transfusion. The availability of closely spaced, sequential samples from commercial plasma donors permitted careful characterization of the window period and of the impact of additional tests. These studies showed that as the sensitivity of antibody tests was increased, the HIV window period was reduced to about 22 days.[19] The impact of the addition of tests for the HIV-1 p24 antigen and HIV RNA was also estimated.[19] Similarly, the dynamics of early infection with HCV and HBV are now well defined.[20] Although data published in 2002 suggested that the benefits of NAT were consistent with projections,[21] this was not the case for HIV-1 p24 antigen, which was detected much less frequently than anticipated. It is possible that because the HIV antigen peak corresponds

Table 14–2 **Results of NAT for HIV and HCV, USA March 1999–April 2002, and for WNV, 2002–2003**

	Donations tested (millions)	Number Confirmed Positive	Rate per Million
HIV	35.87	11	0.31
HCV	36.97	156	4.22
WNV*	5.32	540	101.5

*Data represents collections only during the period that WNV was detected among donors.

Detection of HIV-1 and HCV infections among antibody-negative blood donors by nucleic acid-amplification testing. N Eng J Med 2004;351:760–768.

with the symptomatic phase of early acute HIV infection, the affected donors feel unwell and are less likely to present for donation.

SCIENTIFIC BASIS FOR TEST SELECTION

Determining a Need for Testing

There are a number of levels of decision making relative to testing for transfusion-transmissible infections. At the highest level is the determination to test for a given agent. Many factors are considered in this process, including the potential frequency of transmission of the disease, its severity, and the efficacy of treatment. This is perhaps the most difficult decision to make, and there is no clear guidance, methodology, or prioritization process in place. In fact, in the United States, there are no clear decision-making hierarchies for implementing a new test, although final authority for requiring a test rests with the FDA. During the history of blood testing, there have been examples of voluntary initiation of tests, either by a local decision in one or more blood establishments, or through professional bodies, such as the AABB. In the first of these categories, a number of individual blood establishments independently initiated early testing for ALT, anti-HBc, or HIV-1 p24 antigen. In the past, the AABB, through its standard-setting procedures, has called for testing for ALT and anti-HBc, and more recently, for methods of detecting bacteria in platelet concentrates. In addition, even if it is clear that a preventative measure is required for a given agent, there is no process to make sure that a test will be developed and made available. Conversely, it appears that the development of a test will not necessarily lead to its adoption, at least in the short term. However, the development and implementation of a test for WNV RNA appears to be a good example of a case in which the need was clear, and all stakeholders worked together to achieve an effective outcome.[14]

Although it would seem appropriate to base a decision about test implementation on science and cost-benefit analyses, there is now a much greater tendency to invoke a variant of the precautionary principle. In effect, this tendency translates to implementing some measure to reduce transfusion risk before data are available to define the efficacy of such a measure. The major constraint is that the measure should not have any deleterious effect. It has been argued that the use of this approach has been successful in the case of donor deferral policies for risk of vCJD.[22] However, in this case, the argument was that measures had been taken before the disease had clearly been shown to be transmissible by transfusion. The selected measures had not been shown to be efficacious, so the argument for success was based on the finding of transmission, rather than a demonstration that the measures actually prevented it. If the precautionary principle is used to promote the use of unproven methods, it is important to recognize that the principle is not absolute and that certain constraints should be considered before it is invoked.[23]

Selecting a Test Methodology

Of more scientific interest is the selection of an appropriate methodology to be used to test for any given agent. In the past, this selection was often based on the historic availability of a given technology and its linkage to the discovery or characterization of the agent in question. The classic examples of this approach are the use of nontreponemal tests for syphilis and the implementation of testing for HBsAg. In fact, both of these approaches turned out to be appropriate and successful, but we are now in a much better position to select methods on the basis of the properties of the infectious agent itself, and of its pathology and natural history. Broadly speaking, the approaches are to identify the infectious agent itself, or to focus on the body's reaction to infection with the agent.

Direct Identification of Infectious Agents

Direct detection of the agent itself may involve techniques as simple as visualization, or as complex as nucleic acid amplification. Obviously, direct visualization is unlikely to be sensitive enough to support current needs for blood safety, although it is used in some circumstances—for example, evaluation of donor malaria infection in parts of the developing world. Most current technologies in widespread use involve the immunologic detection of specific antigens and amplification of nucleic acids. Antigen testing has undoubtedly been of greatest use up to the present time and has demonstrated its greatest efficacy in the detection of infection with HBV. Its efficacy is directly attributable to an essentially unique property of HBV infection, which is the synthesis of a great excess of the viral surface antigen. This, in effect, is an amplification mechanism, because immunologically based tests can usually only detect analytes at levels well above the picogram-per-mL range. It is not to be expected that many other infectious agents will be as readily detected through their antigenic components. Nevertheless, HBV has been considered to be a model, and a great deal of effort has been expended on a search for detectable soluble antigens from other transfusion-transmissible viruses. In fact, methods to identify antigens of both HIV and HCV have been successfully developed and deployed. However, the antigenic levels have been low, and their sensitivity in detecting infectivity is greatly surpassed by nucleic acid testing. For example, the maximum sensitivity of a test for HCV core antigen is equivalent to about 30,000 to 50,000 genome copies of RNA, although this sensitivity can be increased by the use of immune complex dissociation techniques.[24] Another issue with antigen detection is that, in general, antigens cease to be readily detectable once a significant level of antibody has developed. Thus, in the absence of methods using immune complex dissociation, antigens are detectable only during the early acute phases of infection. (This is not the case for HBV, because the levels of antigen synthesized during chronic infection are enough to overwhelm the antibody response and lead to a situation of antigen excess.) Thus, with the exception of HBsAg, antigen detection methods are used to supplement other detection procedures by providing for earlier detection of infection and thus reducing the length of the infectious window period. A test for HIV p24 antigen was in use for this purpose for a number of years in the United States and some other countries, but at least in the United States it has been supplanted by the much more sensitive NAT. Some countries have adopted a test for HCV core antigen instead of implementing the more costly and complex NAT. An evolving trend is the development of so-called *combo assays*, which permit the detection of both the viral antigen and the antibody. Such tests offer operational advantages, but they are generally somewhat less sensitive

than individual tests alone. In general, it should not be anticipated that blood product contamination by any emerging infection will be effectively prevented solely by testing for its antigens.

Nucleic acid amplification tests are extremely sensitive, with the theoretical possibility of detecting a single molecule of nucleic acid, although this level is rarely achieved in practice. Conceptually, NAT was introduced into donor testing as a way to increase safety by identifying individuals in the viremic window period. In large part, it appears to have fulfilled this expectation, reducing the estimated risk of transfusion-transmitted HCV from 1 per 200,000 units to 1 per 1,390,000 units, and that of HIV from 1 per 1,048,000 units to 1 per 1,525,000 units.[21,25] However, it is clear that NAT is insufficiently sensitive to identify every infectious blood unit, and it is currently seen as a supplement to conventional immunologic tests for antibodies to HIV and HCV. NAT for HBV DNA is now available and, at the time of writing, one test has been licensed for routine use, but such use is has not been mandated by the FDA. This is the case largely because there appears to be relatively little benefit to implementing this test on pooled samples, relative to the use of highly sensitive tests for HBsAg. Nevertheless, a continuing question is whether NAT could displace currently used serologic tests for any of these viruses. Certainly, it is clear that a proportion of donor samples may have confirmed positive test results for antibodies, but they may be negative for RNA or DNA. This result occurs among about 20% of anti-HCV–positive, and about 0.4% of anti-HIV–positive donors (SL Stramer, unpublished observations). In some, but not all, cases, these findings do represent resolution of infection and viral clearance. Overall, at the time of writing, it seems unlikely that conventional test methods will be eliminated.

The value of NAT for managing emerging transfusion-transmissible infections has been amply illustrated by the U.S. experience with WNV. NAT for this virus was developed by two manufacturers and implemented within 9 months of the recognition of need. It is certainly easier to develop a nucleic acid-based assay than an immunoassay, because it does not require the expression of antigens or the production of antibodies. However, NAT may not necessarily be the most effective solution for all emerging infections. It has been very successful in the case of WNV because the infection itself is acute, and it appears that the period of blood-borne infectivity is restricted to the earliest phases of infection, prior to the development of significant levels of antibodies. In fact, there do not appear to have been any well-documented cases of transfusion transmission of WNV from donors who had developed antibodies to WNV.[14]

Detection of Antibody and Other Responses to Infection

The other broad approach to testing for infectivity is by assessing the body's response to the agent. Most frequently, of course, this assessment is done by detecting antibodies, although other methods have been used or considered. The major benefit of testing for antibodies is that the immune response is a form of amplification: infection with, or exposure to, a modest titer of a microorganism generates levels of circulating antibodies that are readily detectable by relatively simple procedures. Antibody tests have been highly effective as a measure to control transfusion-transmitted infection with a number of agents, but this effectiveness is really confined to persistent infections, such as HCV, HIV, or Chagas disease. In contrast, as pointed out above, antibody testing does not offer any benefit for the prevention of acute infections, as exemplified by WNV, where it appears that infectivity diminishes or disappears as antibody becomes detectable. Clearly, in such circumstances, direct detection of the agent is the preferred approach. More broadly, the use of any given test approach for donor screening should be based on knowledge of the natural history of each particular infection, rather than on the availability of a test method per se.

At the time of writing, there is interest in an entirely different approach to the detection of infection, based on proteomics. Modern technology permits the characterization of actual or relative concentrations of a very large number of proteins (for example, in the plasma). Some of these protein levels may change as a result of infection with a particular organism, and conceptually, at least, it may be possible to identify an infection through a particular pattern of change in the levels or distribution of these proteins. Rapid, simultaneous screening of large numbers of proteins, along with intensive computational capabilities, makes this identification possible. However, this approach has yet to be shown to be appropriately sensitive and specific, or even simple enough, for routine use.

Selecting a Specific Test

The final level of test selection is the choice of which particular manufacturer's test to use. Although it may be argued that in many parts of the world tests must be approved by a regulatory authority, this requirement does not ensure that all approved tests have equivalent performance characteristics. This fact is clearly demonstrated by the differences in analytic sensitivity for licensed (and unlicensed) HBsAg tests reported by the FDA.[26] Consequently, a process of evaluation of test characteristics is desirable in order to inform purchase decisions, in addition to issues of cost and convenience.

For blood screening tests, the key performance parameters are sensitivity and specificity. In the case of most markers, analytic sensitivity directly impacts epidemiologic sensitivity. In other words, a more sensitive test will identify more infected donors. Perhaps the most important aspect of sensitivity is the ability to detect infection at the earliest time, because this detection reduces the length of the infectious window period and hence the risk of transmitting infection to recipients. Sensitivity for early infection is best evaluated against panels of samples taken during seroconversion. Such panels are commercially available and have usually been collected from donors of plasma for further manufacture. It should, however, be noted that in an environment where multiple tests are used for any given infectious agent, the sensitivity of the overall test system is most important. For example, use of NAT may compensate for an antibody test that may not be the most sensitive one available. Another aspect of sensitivity is the ability of a given test to detect different serotypes, genotypes, or mutants of the agents of concern. Most available tests have been designed to have optimal sensitivity for the strains of agent that predominate in the United States. Even though a particular strain or genotype is very rare, there may be benefits to using tests with broader sensitivity. For example, in the United States, potential donors must be deferred if they have a history of travel, residence, or sexual contact in certain African countries where HIV-1 type O is

present, unless a test with FDA-validated claims for group O detection is used.

Test specificity is another critical parameter. Tests with poor specificity result in unnecessary loss of products and their donors, and they require performance of additional confirmatory tests. Furthermore, blot-based confirmatory tests frequently generate indeterminate results that are hard to interpret and which cause unnecessary alarm when donors are notified. The very low prevalence of some infections among blood donors magnifies the impact of poor test specificity. For example, the positive predictive value of a repeat reactive test result for HIV is currently around 5% in the U.S. donor population, even though current tests have good to excellent specificity. A test's specificity is best evaluated by testing many nonreactive samples, preferably from donor populations.

Ideally, assessments of sensitivity and specificity should be made in field conditions. However, doing so may be unrealistic, and decisions may have to be based on available information. Although comparative evaluations of test kits are occasionally published in the open literature, every kit approved in the United States includes a product insert with summary information of the results of the clinical trials that define the claimed performance characteristics for the test. Tests should be expected to meet these performance claims in routine use. Clinical trials for licensure of tests for donation screening require evaluations of test sensitivity and specificity in field conditions, along with evaluations of the impact of samples with interfering substances. Sensitivity evaluations include the use of a wide variety of positive samples representing different genotypes. In addition, a population of high-risk samples is usually tested. Specificity is assessed by testing 10,000 or more routine donor samples. Samples giving positive results must be further investigated and the donors evaluated by follow-up.

TESTS BY AGENT

Hepatitis B Virus

Hepatitis B Immunoassays

The primary means for the detection of hepatitis B infectivity is the test for HBsAg. This antigen is the first serologic marker to appear during acute HBV infection, and it persists during active, chronic infection. It is produced in the cytoplasm of HBV-infected cells, and it is often present in the serum at high levels, even up to micrograms per milliliter. The HBsAg represents the viral coat and is found in the serum or plasma in the form of self-assembled spheres and tubules 22 nm in diameter. It is readily detected by simple, sandwich-type immunoassays using animal antibodies to HBsAg (anti-HBs) as a solid-phase capture reagent and a conjugated anti-HBs as a probe. Conventional assays use either a bead or a microplate well as the solid phase, but tests (particularly automated ones) are increasingly based on microparticle substrates. Similarly, enzyme conjugates and chromogenic detection methods are being replaced by chemiluminescent labels.

Currently available tests have an analytic sensitivity on the order of 0.5 ng/mL, with a range of 0.08 ng/mL to 0.7 ng/mL. The epidemiologic sensitivity and specificity of the test are high. Nevertheless, because the prevalence of positive HBsAg findings in the donor population is quite low, the positive predictive value of the test is also low. Thus, as with any other donor screening test, any repeatedly reactive finding should be confirmed before the donor is notified. Manufacturers of HBsAg test kits also provide confirmatory reagents consisting of specific antibodies to HBsAg. The test is repeated in the presence of the antibody, and a control test is also run using normal serum. If the added antibody inhibits the test signal by 50% or more relative to the control, the reactive result is considered to be confirmed as positive. There are some additional steps that are required in specified circumstances (such as a strong primary test result). It should be noted that very weak reactive signals may also give false-positive results in this confirmatory procedure.

As indicated earlier, testing for anti-HBc was uniformly introduced in the United States in 1986 and 1987. It was originally used to screen for NANB hepatitis infectivity as a result of some epidemiologic correlation between HBV and HCV infection, but this use is no longer considered valid or appropriate. In fact, anti-HBc testing was licensed by the FDA as an additional measure to improve safety with respect to HBV. The core antigen is actually the viral capsid, and antibodies appear early in infection, but after HBsAg. Originally, it was hypothesized that anti-HBc was the only marker detectable during a window period after the decline of HBsAg and before the appearance of the corresponding protective antibody (anti-HBs). Current test methods are so sensitive that this is probably no longer the case. Nonetheless, there are both old and contemporary data suggesting that a minority of donations with anti-HBc as the sole marker of HBV infection may be infectious.[27–30] However, the presence of significant levels of anti-HBs seems to negate the risk of any infectivity through the blood (although not from a transplanted liver).[31] Consequently, in Japan, a country with a high prevalence of HBV infection, donors are tested for HBsAg, anti-HBc, and anti-HBs. All units with detectable HBsAg are discarded, as are those with anti-HBc in the absence of anti-HBs. However, units with both antibodies are used for transfusion.[32]

There are two approaches to anti-HBc testing. The initial test that was developed was an inhibition immunoassay, which is still available. The solid phase has recombinant HBc antigen as a capture reagent, and the probe is a labeled, partially purified anti-HBc antibody. The presence of anti-HBc in the test sample inhibits the signal. Perhaps surprisingly, this test has rather poor specificity, in part because of reduction-sensitive interfering molecules in some samples.[33] Newer versions of the test incorporate reductants, which clearly increase the specificity of the test. However, the inhibition procedure is also quite dependent on good technique, and reproducibility is not optimal. A second test, a direct antiglobulin assay for anti-HBc, is also available; it appears to be more specific than the inhibition procedure. There is no formal confirmatory procedure for anti-HBc, but the use of two different tests may help to increase the predictive value of a reactive result.

Nucleic Acid Amplification Testing for Hepatitis B Virus

A number of NAT procedures for HBV DNA have been developed and, in some cases, put into routine use, particularly in Japan and parts of Germany.[34,35] In the United States, two commercial procedures have been developed and evaluated in clinical trials.[36] At the time of writing (2005), one of these procedures has been licensed by the FDA. However,

the FDA did not specifically require its use. Clinical trials of the licensed test using minipool procedures did result in the detection of HBV DNA–positive, serology-negative donations at a frequency of about 1 per 340,000 donations. In general, minipool testing for HBV DNA is considered to have a sensitivity similar to that of the most sensitive tests for HBsAg, and there is considerable debate about the real safety benefits of minipool NAT for HBV in the United States. It must be remembered that anti-HBc testing of donors is in routine use in the United States, and studies have shown that fewer than 1% of anti-HBc-reactive donations have detectable HBV DNA. Consequently, minipool NAT for HBV may have more value in an environment where anti-HBc testing is not in use. It is considered likely that the use of individual donation testing for HBV DNA would offer some increased safety, because the increased sensitivity may decrease the length of the window period. Finally, HBV NAT of plasma for further manufacture has been implemented using relatively large pools of samples (i.e., 512 to 1200).

Other Hepatitis B Virus Tests

There are other tests for markers of HBV infection, but, in general, they have little current relevance to transfusion medicine, at least in the United States. As pointed out earlier, tests for anti-HBs are available, and a positive result usually (but not always) signifies a resolved infection and the absence of circulating virus.[32] Indeed, the presence of anti-HBs may not signify complete elimination of HBV, because the virus may still be present in the liver; transplanted organs from donors with anti-HBs can result in HBV infection in a susceptible recipient.[31] Nonetheless, anti-HBs testing may be used to identify anti-HBc–reactive donations that are safe for transfusion, as in Japan. There are commercially available tests for immunoglobulin M anti-HBc, and this test is useful for diagnosis of acute HBV infection. Tests for the hepatitis B e antigen are of some value in defining the severity of an infection, but the value of a test for the corresponding antibody (anti-HBe) is less clear.

Hepatitis C Virus

HCV Immunoassays

The primary screening and diagnostic test for HCV infection is an antiglobulin EIA for antibodies to the virus. As of the end of 2005, only two tests were available in the United States. Both use immobilized, recombinant viral antigens as the capture reagent and an anti-immunoglobulin conjugate as the probe. One test is defined as a version 2.0 test, and the other as a version 3.0. Both tests use antigens representing the core and NS3/NS4 regions of the viral genome, and the 3.0 version includes an NS5 peptide. In comparison, the first test to be licensed (termed 1.0) used only a single peptide in the capture reagent. This HCV 1.0 test, although a considerable advance on surrogate testing, lacked both sensitivity and specificity. Subsequent versions are much improved with respect to both of these characteristics.

One licensed supplementary test for anti-HCV is available in the United States. This test is an immunoassay consisting of a nitrocellulose paper strip bearing HCV peptides at specified locations. There are also controls to ensure that the test is performed properly and to identify reactions due to antibodies to superoxide dismutase (SOD), a carrier protein for expression of some of the peptides. The strip is exposed to a test sample, and any adherent antibodies are detected and visualized by use of an antiglobulin conjugate and a chromogenic substrate. The test is designed to complement the version 3.0 EIA and consequently uses essentially the same peptides. Clearly, the test was developed to dissect out and identify the presence of antibodies to different viral epitopes. In common with the Western blot, this approach has two deficiencies: (1) it is a subjective test, and (2) it does not generate outcomes with unequivocal interpretations. That is, results may be defined as nonreactive, positive, or indeterminate. A positive test is defined on the basis of at least two bands with a density greater than or equal to that of the low-positive control, but in the absence of an SOD band. A negative result is defined as one or more bands with a density less than that of the low-positive control. A result is defined as indeterminate if there is only one band with a density greater than or equal to that of the weak-positive control or if an SOD band is present, irrespective of other band patterns. An indeterminate result does not clearly establish the presence or absence of current or prior infection with HCV. In testing donors, about 20% of EIA repeat-reactive donations are found to be indeterminate, but only about 1% of these donations are positive for HCV RNA by polymerase chain reaction (PCR).[37,38]

Hepatitis C Virus Nucleic Acid Amplification Testing

At the time of writing, two commercially available NAT procedures are in use for testing donor blood for evidence of HCV infectivity.[16] One is a PCR procedure that is conducted on RNA extracted by standard chemical methods from pools of 24 plasma samples. The other approach uses a transcription-mediated amplification procedure on nucleic acid preparations made by a solid-phase, probe-capture method. Both approaches are successful in detecting HCV antibody–nonreactive, RNA-positive window–phase donations. Furthermore, both methods seem to have the same performance characteristics when the different sensitivities of the version 2.0 and 3.0 EIAs are accounted for. Following infection, HCV RNA levels increase rapidly and reach values of 10^5 to 10^7 copies/mL during the period about 40 to 50 days before the appearance of detectable HCV antibody. In a review of national experience with NAT, Stramer and colleagues[16] showed that the detection rate for HCV RNA was about 1 in every 230,000 seronegative donations.[16] Accepted testing algorithms for blood donor screening differ somewhat from those for diagnosis or screening of the general population, inasmuch as the NAT procedures have not been formally accepted as part of the confirmatory process for donors. This subject is discussed in more detail in Chapter 44.

Although not in widespread use, immunologic tests for the HCV core antigen have been developed, with a sensitivity that is approximately equivalent to the detection of 30,000 to 50,000 copies of HCV RNA. Although less sensitive than NAT for HCV RNA, core antigen tests nevertheless are capable of substantially reducing the infectious window period.

Human Immunodeficiency Virus

Immunoassays for Human Immunodeficiency Virus Antibodies

As a direct result of the discovery of HIV, the causative agent of AIDS, the first tests for antibodies to this virus were

licensed for donor screening in early 1985. All of the initial tests were antiglobulin EIA procedures using viral lysate as the solid-phase capture reagent and enzyme-conjugated antiglobulins as the probe. Early results using one of these procedures nationwide revealed that the prevalence of seropositive donations was 0.038%.[39] Tests for antibodies to HIV have been continuously upgraded. During this process, there have been two major changes. First, in 1992 the FDA required that blood donor testing should include a means of detecting infection with HIV-2. This goal was achieved by the development of combination ("combo") tests designed to identify antibodies to both viruses in the same test. Second, and in some cases as a means of satisfying this requirement, some of the tests evolved to a direct test in which both the capture reagent and the labeled probe were viral peptides (usually prepared by recombinant techniques). These approaches led to much-increased sensitivity, cutting the seronegative window period by as much as 23 days.[40] As a result of careful and intensive approaches to donor selection and questioning and of continued testing, fewer than 1 in 25,000 donations are currently confirmed positive for anti-HIV.

Two tests are licensed for confirmatory or supplemental testing for anti-HIV. The one more commonly used is the Western blot, essentially a research test that was reported in the earliest publication on HIV antibody testing.[41] Also approved for use is an indirect immunofluorescence procedure. The Western blot is similar to the strip immunoassay already mentioned, in that it identifies the presence of antibodies to individual viral components. The blot procedure involves separation of viral components by electrophoresis on polyacrylamide gel, followed by transfer (blotting) to a nitrocellulose paper. A strip of the paper is exposed to a test sample, and adherent antibodies are detected and visualized by the use of an appropriate conjugated antiglobulin.

A number of attempts have been made to define an effective set of interpretive criteria for the HIV blot, but none has been fully effective.[42–47] The criterion in current use was developed by the Centers for Disease Control and Prevention and the Association of State and Territorial Public Health Laboratory Directors. A positive finding is defined as the presence of at least two of the following bands at an intensity equal to or greater than that of the weak-positive control: p24, gp41, and gp120/160. A blot with no visible bands is considered to be negative, and any other band pattern is interpreted as indeterminate (even if the bands are nonviral).[47] In fact, the current approved criterion may lead to false-positive outcomes in as many as 10% of donor samples with a positive blot interpretation.[46,48] Indeterminate outcomes are also frequent; in the American Red Cross system, only 4.8% of EIA repeatedly reactive samples are found to be positive on the blot, 44.2% are negative, and 51% are indeterminate. Essentially all of the reactions in the indeterminate group are unrelated to HIV infection, but current recommendations permit them to be resolved only on the basis of follow-up. A clear advantage of the immunofluorescence alternative method is the much lower frequency of indeterminate results. The interpretation of HIV antibody test results is complicated by the requirement to evaluate EIA repeatedly reactive samples for evidence of HIV-2 infection using a second test based on a viral lysate. There are no licensed supplemental tests for HIV-2, and some individuals may be inappropriately notified that they have been infected with HIV-2 despite its extreme rarity in the U.S. donor population.

Human Immunodeficiency Virus p24 Antigen Testing

The inability to detect HIV in the infectious window period has engendered considerable concern since 1985. As pointed out earlier, the sensitivity of antibody tests has been improved, so that the window period has been halved. Nevertheless, the risk is still unacceptable. Although it was known that the soluble HIV-1 p24 antigen could be detected during the window period, an extensive study published in 1990 did not suggest that implementation of the antigen test for screening would have any appreciable yield.[49] Subsequently, the issue was reevaluated, and antigen testing was implemented in 1996. Despite predictions that approximately 5 to 10 antigen-positive, antibody-negative donations would be identified each year, the actual detection frequency has been only 1 in 4 million to 9 million donations.

Human Immunodeficiency Virus Nucleic Acid Amplification Tests

As is the case for HCV, NAT has been implemented for the detection of HIV RNA. The procedures used are those described previously for HCV. Subsequently, NAT for HIV was licensed, and two tests are available for routine use. During the period of use of these tests under IND, it was shown that all p24 antigen-positive samples were also clearly reactive by NAT, and the use of the p24 test has now been discontinued. Reviews of national data have shown that 1 in 3.1 million donations are HIV RNA positive, but seronegative.[16] Studies have shown that HIV RNA levels increase quite rapidly and normally reach 10^4 to 10^6 copies/mL before the appearance of anti-HIV antibodies. Nevertheless, there have been a handful of cases in which transfusion transmission of HIV has occurred from NAT-nonreactive blood components.[50–52] Again, the results of NAT have not been formally approved as a supplement to the serologic test results, even though such information would be of clear relevance in notifying and counseling seropositive donors.

Human T-Lymphotropic Virus

Although HTLV-1 was the first human retrovirus to be identified, donor testing was not initiated until 1988. Seroprevalence studies indicated that approximately 0.025% of the donor population had evidence of infection with the virus.[13] In actuality, as a result of the strong sequence and antigenic homologies, the tests originally developed to detect antibodies to HTLV-1 were also able to detect many (perhaps most) infections with HTLV-2. Although the viruses differ epidemiologically, there are insufficient data to determine the extent to which their pathologic outcomes differ.

Tests for antibodies to HTLV-1 and HTLV-2 are generally similar to the earliest tests for HIV antibodies. That is, they rely on a viral lysate as the capture reagent, and adherent donor antibodies are identified with an antiglobulin conjugate. In 1998, the FDA required that blood donations be additionally evaluated for the presence of antibodies to HTLV-2 using a test formally approved for that purpose. This requirement necessitated the development of tests that included specific HTLV-2–derived antigens, and manufacturers developed combo tests for this purpose. Consequently, available tests are designed for the detection of HTLV-1/HTLV-2 antibodies.

There are no licensed confirmatory or supplemental tests for the EIA procedures. Western blot tests are commercially available for use under research or IND protocols, but their performance characteristics are far from optimal. In fact, in the American Red Cross system, only 9% of EIA repeatedly reactive samples are positive by blot, 19.3% are negative, and the remaining 71.7% are indeterminate.[38] Radioimmunoprecipitation has been used to supplement these procedures, but this technique is more complex and arduous than the Western blot. A final problem is that additional tests may be required to distinguish HTLV-1 and HTLV-2 infections. A specific viral peptide–supplemented blot is designed to differentiate these two infections, but it is not readily available to blood collectors. It is, however, reasonable to ask whether there is any clear medical benefit to distinguish between these viruses; notification policy does not differ greatly.[53] NAT is available experimentally, but it appears unlikely to be adopted for screening donations.

Syphilis

Although (or perhaps because) testing for syphilis was the first procedure to be implemented for blood safety, it is now the least understood and least justified test in use. The nature and properties of serologic tests for syphilis are described in much greater detail elsewhere.[54] Initially, donor testing was undertaken using nontreponemal tests, such as the rapid plasma reagin (RPR) test. Although these tests were markedly nonspecific, they had the advantage of identifying primarily active or recent infections. Over the past 10 to 15 years, most blood collection agencies have adopted treponemal tests, mainly because they are adaptable to use on automated instruments, including those routinely used for blood typing. Treponemal tests generally indicate current and distant infection, even after successful treatment. Repeatedly reactive screening test results are generally confirmed or supplemented by the use of fluorescent treponemal antibody tests, treponemal EIA tests, or nontreponemal assays. The frequency of reactive screening test results among Red Cross donations is about 0.18%. Of these results, about 46% are confirmed by a fluorescent treponemal antibody absorption (FTA-ABS) test. Among the confirmed samples, 23% are RPR reactive. Even so, only about 50% of donors with an FTA-ABS–confirmed positive result report a history of syphilis.

Evolving data suggest that few, if any, donors who test positive for syphilis antibodies have detectable *Treponema pallidum* DNA or RNA in their circulation.[55] In contrast, many individuals identified through sexually transmitted disease clinics are clearly bacteremic. The FDA has indicated its willingness to evaluate data with a view to reconsidering the need to continue routine syphilis testing for blood donors. It should be noted that, although a history of syphilis results in a 1-year deferral because of concerns that active syphilis might correlate with increased risk for HIV, there is no evidence that a positive test result for syphilis has any meaningful association with window-phase HIV infection.[56]

Cytomegalovirus

Cytomegalovirus (CMV) infection is usually relatively benign, but it can have profound and life-threatening effects on persons with a compromised immune response, including low-birth-weight infants. The virus is ubiquitous, and seroprevalence rates of 50% or more are common among adult populations. For many years, the use of CMV-seronegative blood components has been recommended for particular groups of patients at risk for serious CMV disease.[57,58] It has been suggested that the use of leukoreduced components may similarly protect these vulnerable groups. Nevertheless, CMV testing continues to be used.[59] Both particle agglutination and EIA tests are available. Seronegative products are labeled as such, but there is no corresponding labeling of seropositive products, which are freely used for recipients who are not considered to be at risk. There is no program for donor notification or deferral for reactive CMV antibody tests. The performance characteristics of tests may differ, and there is no definitive "gold standard." Even the use of nucleic acid amplification techniques has generated results that are not always readily interpreted, perhaps as a consequence of interlaboratory variation in testing.[60]

SURROGATE TESTS

The usual approach to testing blood for transfusion is to apply an assay that identifies a specific marker of the infectious agent concerned. Serologic tests depend on the detection of circulating antigens or antibodies, and NAT methods provide direct detection of the pathogen's RNA or DNA. However, NANB hepatitis and AIDS were recognized as transfusion-transmissible diseases before any specific markers had been identified. In these cases, surrogate tests were considered or implemented. In the case of NANB, key studies clearly documented an association between elevated ALT levels in donors and the development of NANB in the recipients of the donations. Somewhat surprisingly, subsequent analysis showed a similar but nonoverlapping relationship between donor anti-HBc and recipient NANB. Although it was widely recognized that these tests were neither specific nor sensitive for NANB, they were projected to reduce the incidence of such post-transfusion infection by up to 60%, and testing for both markers was introduced during 1986 and 1987. Such projections were subsequently validated when tests for anti-HCV came into use.[61]

During the early years of the AIDS epidemic, it was recognized that individuals with the disease were often reactive for anti-HBc. Although a relationship between anti-HBc in donors and transmission of AIDS to recipients was understandably not demonstrable, some blood centers, particularly in the San Francisco Bay area, implemented anti-HBc testing as a surrogate.[28,62] Further expansion of this measure was overtaken by the recognition of HIV and by the anticipated availability of a specific test. Other measures based on some of the clinical characteristics of AIDS, such as changed T-cell subset ratios, were also proposed as surrogates and implemented in at least one location.[63]

Surrogate tests are inevitably less than satisfactory, usually failing to demonstrate adequate sensitivity or specificity. However, it should be recognized that perceptions have changed materially over the past 2 decades, and there is little doubt that surrogate tests would be seriously considered in the future. One example is the potential use of surrogate markers as a means of identifying individuals in the early stages of disease attributable to transmissible spongiform encephalopathies.

DONOR AND PRODUCT MANAGEMENT

Testing is a key aspect of blood safety. Consequently, blood components are managed very conservatively with respect to test results. As pointed out earlier, a blood donation is discarded when found to be repeatedly reactive in a test. For the majority of assays, there is also a requirement to identify, retrieve, and quarantine any in-date products from prior donations from the affected donor. This action must be taken within a 3-day time frame, but it is not necessary if negative confirmatory or supplementary test results are available within this time.

A confirmed positive test result for HIV or HCV in a repeat donor triggers *lookback*. This process is designed to identify the recipients of prior donations from an individual now found to be seropositive. Such donations may have been in the infectious window period, may have been tested by a less-sensitive version of the test, or may have been given before the implementation of the test in question. Lookback may also be triggered by a report that implicates a donor in post-transfusion disease.

Donors with repeatedly reactive test results must be deferred from all further donations, and records must be kept to ensure that they are deferred. Clearly, this process results in the loss of many uninfected donors. At the same time, there is little point in continuing to collect blood from an individual who continues to generate false-positive test results, because the donations could not be used. In some circumstances a test that yields a false-positive result is not repeated, and so-called "reentry algorithms" have been developed to permit continued donation. These algorithms generally apply only to donors with repeatedly reactive screening test results that are negative in a licensed confirmatory or supplemental test. After a suitable waiting period, the donor must test nonreactive on screening and supplemental or confirmatory tests before being permitted to give blood again. Acceptable reentry protocols are published and updated by the FDA.

C. Regulatory, Quality, and Legal Principles

Chapter 15

Regulatory Principles and Issues Central to Blood Banking and Transfusion Medicine

Shealynn B. Harris • Christopher D. Hillyer

INTRODUCTION

Regulation is a government's oversight and control of a nongovernment entity's operations and practices through the enactment and enforcement of laws (i.e., regulations). Compliance with these legal requirements is not voluntary, and the potential consequences for a failure to comply with regulations include civil and criminal penalties. In general, the impetus for enacting regulatory legislation is the protection and promotion of public welfare; thus, regulations focus primarily on the overall safety of commercial and manufacturing operations, along with some professional services that directly impact the public welfare.

In the United States, the authority for federal regulatory oversight and enforcement is designated to a government agency; this agency is typically within one of the departments of the executive branch that is directed by a secretary, an appointee of the president of the United States. There are some exceptions to this regulatory organizational structure; for example, the Nuclear Regulatory Commission (NRC) is independent of a department and is led by a group of five commissioners who are all appointed by the president.[1] Although regulation is often more apparent at the federal level, regulation also occurs at the state level. There are similarities and overlap between federal and state regulation, a situation that is apparent in the parallel organizational structure of federal and state regulatory agencies and in the general purpose of federal and state regulatory code. In addition, federal authorities often partner with states through cooperative agreements to perform specific regulatory functions. However, for some operations and practices, it is the state government, and not the federal government, that sets regulations and maintains sole regulatory authority; examples include medical licensing, and in the case of blood establishments, the lower age limit for volunteer blood donation. The key federal regulatory agencies that have jurisdiction within blood banking and transfusion medicine are listed in Table 15–1.

As seen in Table 15–1, the U.S. blood industry as a whole is accountable to a variety of regulatory agencies. However, for an individual blood establishment, the extent of each agency's regulatory oversight depends on the breadth of the regulated establishment's operations and processes. In general, all U.S. blood establishments are subject to regulatory oversight by the Food and Drug Administration (FDA) for blood manufacturing and by the Centers for Medicare and Medicaid Services (CMS) for clinical laboratory testing.

This chapter focuses primarily on the FDA and the CMS in terms of agency structure, regulatory code, compliance oversight, and enforcement practices that are specific to the blood industry. The specific regulatory activities of the Department of Transportation (DOT), Occupational Safety and Health Administration (OSHA), and NRC that relate directly to blood establishments, blood manufacturing, and blood components are summarized in Table 15–1 and are not further addressed in this chapter. Finally, this chapter does not address regulation of non-U.S. blood banks and transfusion services, which range from highly developed to virtually nonexistent, depending on the location, nor does this chapter address the practice of medicine including aspects of transfusion medicine practice, because these aspects are not regulated by the government.

Regulation is sometimes confused with, or used as synonymous with, accreditation. *Accreditation* is a mechanism by which an organization's or an industry's practices are surveyed and formally approved by a private accrediting agency that promotes standards of practice for a specific industry or profession. In contrast to regulation, the accreditation process is voluntary, and failure to comply is not grounds for civil or criminal action. These private agencies not only serve an important role to the regulated entities, but they can also serve as a check and balance structure for government regulators. A more detailed discussion of accreditation and quality is presented in Chapter 16.

Table 15–1 **Federal Regulatory Agencies in Blood Banking and Transfusion Medicine**

Agency	Key Legislation	Regulatory Code (Title of CFR)	Applicability of Regulation
Department of Health and Human Services (HHS)			
Food and Drug Administration (FDA)	Federal Food Drug and Cosmetic Act of 1938 (FDC) Public Health Services Act of 1944 (PHS)	Title 21	Blood and blood manufacturing
Centers for Medicare & Medicaid (CMS)	Clinical Laboratory Improvement Amendment of 1988 (CLIA)	Title 42	Clinical laboratory testing
Department of Labor (DOL)			
Occupational Safety & Health Administration (OSHA)	Occupational Safety and Health Act of 1970 (OSH)	Title 29	Personnel safety (e.g., biohazard information, personal protective equipment (PPE), postexposure prophylaxis)
Department of Transportation (DOT)			
Pipeline and Hazardous Materials Safety Administration (PHMSA)	Federal Hazardous Materials Transportation Law (HAZMAT)	Title 49	Packaging, labeling, transport of biohazardous materials
Federal Motor Carrier Safety Administration (FMCSA)	Motor Carrier Safety Improvement Act of 1999	Title 49	Commercial drivers
Nuclear Regulatory Commission (NRC)	Nuclear Regulatory Legislation (NUREG)	Title 10	Free-standing irradiators

BLOOD AND BLOOD MANUFACTURING: THE FDA

Background

The federal government has regulatory authority over drugs, biologics, and devices, as mandated by the Federal Food, Drug, and Cosmetic (FDC) Act of 1938 and the Public Health Services (PHS) Act of 1944.[2] The FDA, an official agency of the Department of Health and Human Services (HHS), is the responsible body for the regulatory oversight and compliance enforcement of its regulations for drugs, biologics, and devices. Along with its regulatory duties, the FDA also engages in scientific and research endeavors, and it serves as an information resource for industry, health care, and the public.

Regulatory Organization

The FDA is organized into *offices*, which manage and direct FDA operations, and specialized program *centers*, which oversee the specific products regulated by the FDA.[3] For all FDA-regulated products and industries, the Office for Regulatory Affairs (ORA) serves as the lead office for compliance assurance.[4,5] The ORA's principle duty is the management and coordination of FDA regulatory field operations. These operations include routine inspections of registered and licensed facilities and compliance enforcement activities, such as assistance with legal and criminal investigations.[6]

Each regulated product and industry is also assigned to a specialized program center that is dedicated to non–field-based compliance management, regulatory guidance, and research efforts. The Center for Biologics Evaluation and Research (CBER) is the specialized program center committed to regulatory oversight of all biological products, including blood, vaccines, cellular therapies, gene therapies, tissues, and related devices.[4,7] CBER's research operations are further divided into offices and divisions. The Office of Blood Research and Review (OBRR) conducts research activities related to blood and blood safety through two divisions, the Division of Hematology and the Division of Emerging and Transfusion Transmitted Diseases.[8]

Regulatory Code

Although considered a biological product from an FDA organizational standpoint, in terms of legislation, blood is viewed as both a drug and a biological product. Accordingly, the legal requirements for blood products and blood manufacturing are contained in the FDC Act, which applies to drugs and devices, and the PHS Act, which applies to biologics. The specific federal statutes and amendments that pertain to blood and blood manufacturing are codified in Title 21 of the CFR in Parts 210 and 211 (drugs) and 600 to 680 (biologics).[9]

The entities and processes subject to this regulatory code are broadly defined by the FDA within the CFR and more clearly described in related compliance documents. According to the FDA, a *blood establishment* is "a place of business under one management at one general physical location." The term includes among others, human blood and plasma "donor centers, blood banks, transfusion services, other blood manufacturers and independent laboratories that engage in quality control and testing for registered blood product establishments."[10] For the purposes of FDA registration and compliance oversight, the types of blood establishments, as listed in Table 15–2, are more specifically defined by the FDA in terms of the extent of an establishment's manufacturing processes and level of manufacturing complexity.

Table 15–2 **FDA-Defined Blood Establishments and Registration Requirements**

Establishment	Definition	FDA Registration Requirements
Blood Bank, Blood Center (foreign and domestic)	A facility, sometimes located within a hospital, that engages in the manufacture of blood and blood components including: collection processing of blood components product testing compatibility testing storing distributing of blood products to consignees	Required to register
Blood and Plasma Broker	Takes physical possession of blood products or engages in any manufacturing step. Arranges for the sale or shipment of product.	Required to register Exempt if activities restricted to the arrangement of sale or shipment of products
Component Preparation Facility	Prepares components from blood collected at a mobile or fixed collection site and operates under the control of a parent blood bank or blood center	Required to register through parent establishment
Contractor	Person or entity that performs part or all of the steps in the manufacture of a licensed product or that performs a service for a blood or blood component manufacturer	Required to register Manufacturer and contractor share responsibility for product quality, however the manufacturer is ultimately responsible
Distribution Center or Depot	Stores blood and blood components under specific, controlled conditions for redistribution (intrastate or interstate) to final users and operates under the control of a parent blood bank or blood center	Required to register through parent establishment
Donor (Collection) Center	Fixed location that collects blood from donors by manual or automated methods and operates under the control of a parent blood bank or blood center. May operate blood mobiles or mobile blood drives	Required to register through parent establishment
Hospital Transfusion Service	Performs compatibility testing of (cross matching) for blood and blood components, but does not: routinely collect allogeneic or autologous blood process whole blood into componentswash components, prepare plasma cryoprecipitate reduced or leukocyte reduced products, or irradiate blood products May perform: product pooling of platelets or cryoprecipitate compatibility testing transfusion product thawing division of products preparation of recovered plasma or red blood cells from whole blood collected by a blood bank	Not required to register if the parent hospital participates in the Medicare reimbursement program Inspection responsibility granted to the CMS through a 1980 MOU
Indian Health Service (IHS) Hospital	Blood establishments maintained within the IHS See Blood Bank and Hospital Transfusion Service	
Military Blood Bank and Transfusion Service	Blood establishments, foreign and domestic, maintained by the Department of Defense	All foreign and domestic establishments must register Inspections are NOT unannounced; inspectors must notify respective military contacts 30 days before initiating an inspection
Testing Laboratory	Perform testing for a blood bank which may include testing for: infectious diseases donor suitability and donor reentry product quality	Required to register No registration is required if only testing patient samples or performing syphilis confirmatory tests
Veterans Health Administration Medical Center (VHAMC)	Blood banks and hospital transfusion services maintained within the VHAMC	All VHAMC blood banks and hospital transfusion services must register
Other Blood Establishment	Nonhospital-affiliated establishments that collect blood or prepare blood cells, serum, or plasma for "further manufacture" into drugs or devices	Required to register

Adapted from FDA Compliance Program Manual. Chapter 42: Blood and Blood Products: Inspection of Licensed and Unlicensed Blood Banks, Brokers, Reference Laboratories, and Contractors - 7342.001. FDA Office of Regulatory Affairs. Available at http://www.fda.gov/cber/7342001bld.htm. Accessed Oct. 12, 2005.

In order to operate legally in the United States, a blood establishment must comply with the specific blood manufacturing regulations outlined in the CFR, which include general criteria for licensing, registration, product quality, and component production. In addition to the CFR, which is updated annually, the FDA announces changes to regulations in the *Federal Register*, an official, daily publication of the federal government in which finalized rules and regulations, proposed regulations, and notices of regulatory agencies are posted. The final rules and regulations that are published in the *Federal Register* are incorporated into the CFR with the annual update. Electronic copies of both the CFR and recent editions of the *Federal Register* are available on the FDA website (http://www.fda.gov).

The regulatory requirements in the CFR are stated in broad, general terms. To assist blood establishments with interpretation, standardization, and implementation of regulatory requirements, CBER publishes *guidance documents* that provide background, explanation, interpretation and recommendations for more specific industry procedures and processes. Although not technically legally binding, guidance documents are considered by many to be standards for the blood industry and current good manufacturing practice (cGMP). Guidance documents for the blood industry are available on the CBER website (http://www.fda.gov/cber/guidelines.htm).

Current Good Manufacturing Practice

With regard to blood and blood establishments, relevant sections of the CFR focus primarily on cGMP. In general, cGMP requirements are set forth to ensure the safety, quality, identity, potency, and purity of drugs and biological products, also referred to as *SQuIPP*, in the blood industry.[11,12] More specifically, cGMP regulations are established for key areas of the blood manufacturing process that affect SQuIPP (Table 15–3). If a blood establishment fails to comply with cGMP, the manufactured product may be considered adulterated, and the establishment is subject to regulatory action. To effectively oversee blood establishment compliance with cGMP, the FDA employs several controls, which include registration, licensing, adverse event investigations, and facility inspections.

Blood Establishment Registration and Licensure

Registration

Under the FDC Act, all blood establishments are required to register with the FDA and submit a list of all products commercially distributed within 5 days of initiating manufacturing operations (see Table 15–2).[13] Manufacturers can register by completing either a paper Form FD-2830 (Blood Establishment Registration and Product Listing) or the electronic blood establishment registration (eBER) form on the FDA website. Certain blood establishments and blood distributors are exempt from CBER registration; these are facilities that do not engage in FDA-defined manufacturing activities that require a higher level of technical complexity or proficiency.[14] Manufacturing steps that are considered exempt are routine compatibility testing, product pooling, product thawing, and transfusion. A blood establishment that does not collect blood and restricts its operations to the above activities (e.g., a hospital transfusion service) is deemed exempt if its parent hospital participates in the Medicare reimbursement program. However, if the blood establishment performs more complex steps, as above, including but not limited to washing, irradiation, or preparation of plasma cryoprecipitate–reduced or leukocyte-reduced products and is not affiliated with a hospital in the Medicare reimbursement program, it is required to register with CBER. Exempt establishments are surveyed by the Center for Medicare and Medicaid Services (CMS) for regulatory compliance and are not routinely inspected by the FDA[15] unless just cause requires FDA inspection (e.g., a transfusion-related fatality).

Licensure

In addition to being registered, if a blood establishment engages in interstate commerce of a blood product, under Section 351 of the PHS Act, it must obtain a biologics license.[16] In December 1999, in an effort to improve regulatory efficiency as mandated by the FDA Modernization Act of 1997 (FDAMA), the previously separate establishment license application (ELA) and product license application (PLA) were consolidated into a single biologics license application (BLA).[17] CBER oversees the BLA process, which requires submission of specified documents and a prelicense inspection of the blood establishment. Once an establishment is licensed, any intentional changes to the manufacturing process that may impact product safety, purity, and potency must be reported to the FDA through CBER. Manufacturing changes are categorized into major, moderate, and minor, according to the effect that the change will have on the product. The reporting action that the manufacturer takes is based on the category of change. CBER provides a guidance document to help blood establishments with the process for reporting a change to an approved BLA.[18]

Table 15–3 **A Summary of the Key cGMP Areas Referred to in 21 CFR 210, 211, and 600**

Organization and Personnel
Buildings and Facilities
Equipment
Components, Containers, and Closures
Production and Processing
Packaging and Labeling
Quarantine, Storage, and Distribution
Testing
Records and Reports
Returned and Salvaged Products

Facility Inspections and Compliance Enforcement

All registered, unlicensed and registered, licensed blood establishments are required to submit to routine, unannounced FDA inspections,[19] which are performed at a minimum of every 2 years. The only exception to unannounced inspections is for military blood establishments, for which the FDA must give at least 30 days notice prior to the inspection.[15] The primary objective of the inspection is to ensure SQuIPP by evaluating compliance with cGMP and thus the appropriate sections of the CFR. To focus on critical areas of blood safety, the FDA has identified five "blood systems" and five "layers of safety" (listed below) on which their inspection strategy is based.[15] The five blood systems are Quality Assurance, Donor (Suitability) Eligibility, Product Testing, Quarantine/Inventory Management, and Production and Processing. The five layers of safety are Donor Screening,

Donor Deferral, Product Testing, Quarantining, and Monitoring and Investigating Problems. The extent of the inspection is determined by the blood establishment's specific manufacturing activities and is categorized by levels. A Level I inspection is a comprehensive assessment and requires an evaluation of compliance with all five systems. A Level II inspection is a more streamlined process that involves a review of three of the five blood systems.

On arrival for inspection of a blood establishment, the ORA investigator must provide a Form 482 (Notice of Inspection) that identifies the facility, the inspector, and the legal statutes by which the inspection is authorized.[20] This form must be signed by a facility representative or employee, often an individual of fairly high rank, indicating his or her recognition of the official nature of the inspection. On completion of the inspection, the inspector submits Form 483 (Inspectional Observations), which is a list of any observations of possible compliance violations.[20] This form is also signed by a facility official and acknowledges receipt of Form 483. Form 483 is not a final document of noncompliance, and the manufacturer may submit any objection to the observed violations or a plan for corrective action. Then, in consultation with ORA regional (or national, if needed) leadership and after final review, a formal inspection report is issued. After this compliance evaluation is completed, and if the facility is found to be in violation, the ORA may then begin compliance enforcement. The ORA's enforcement activities include advisory, administrative, and/or judicial actions.[21–23] The primary advisory action is a warning letter, which specifies significant regulatory violations and the necessity for prompt and adequate corrective action. If appropriate action is not taken by the manufacturer, or the action does not satisfactorily correct the violation, the ORA can then proceed with administrative and/or judicial actions, which include citations, license revocation or suspension, product recall or destruction, civil penalties, seizures, court action, and criminal prosecution.

In addition to the above enforcement activities, if a blood establishment fails to comply with regulations after multiple enforcement actions, the FDA may file a "Consent Decree of Permanent Injunction" (also known as a "Consent Decree"), which is a court order approved by a judge. A Consent Decree is a legally binding agreement, overseen by the court, between the FDA and a blood establishment that contains specific requirements and timelines for corrective action of regulatory violations. The Consent Decree defines the way in which the establishment must conduct its business while under the Consent Decree and allows for more frequent and in-depth FDA inspections. In addition, the Consent Decree defines the penalties, such as fines, placed on the establishment while it is under the Consent Decree. If the establishment satisfactorily meets the requirements outlined in the Consent Decree, the establishment will be released from the Consent Decree and considered "in good standing" by the FDA. Because the Consent Decree is a court order, if the establishment fails to comply with the Consent Decree, it is considered "in contempt of court," which is a criminal offense.

LABORATORY TESTING: CLIA AND CMS

Background

With the passage of the Public Health Service (PHS) Act of 1944, the federal government established regulatory authority over clinical laboratory facilities and, more specifically, set forth the requirements for certification of such facilities to operate legally in the United States. Under Section 353 of the PHS Act, the federal government introduced the following key certification requirements: (1) submission of records for types of tests performed, methodologies, and personnel training and experience; (2) accreditation by a government-approved, nonprofit, private accreditation body; and (3) participation in a proficiency testing program through a government-approved, nonprofit, private organization.[24,25] Furthermore, the PHS Act granted authority to the Department of Health and Human Services (HHS) for the oversight of clinical laboratory certification, development and promulgation of quality standards for clinical laboratory test performance, and inspection of clinical laboratory facilities and records.

In 1988, Congress passed the Clinical Laboratory Improvement Amendments of 1988 (*CLIA* or *CLIA 88*) in an effort to ensure the continuous improvement of the quality of clinical laboratory test performance, with a primary focus on the enhancement of test accuracy, reliability, and result turnaround time.[26] Furthermore, CLIA established parameters for the applicability and extent of clinical laboratory regulations by categorizing tests into levels of complexity.

Regulatory Organization

The HHS is charged with overseeing and providing services that relate to public health and welfare. The responsibilities for specific regulatory oversight functions and public services are divided among the twelve agencies within the HHS, each of which has a designated focus area. With regard to regulation of clinical laboratory testing, the HHS has charged its Centers for Medicare and Medicaid Services (CMS), formerly the Health Care Financing Administration (HCFA), with the authority for general CLIA implementation and oversight.[26] In addition, the HHS has given specific CLIA responsibilities to its Food and Drug Administration (FDA) for test complexity categorization, and to its Centers for Disease Control and Prevention (CDC) for convening the Clinical Laboratory Improvement Advisory Committee (CLIAC), which provides technical and scientific advice that relates to CLIA.[26]

The responsibilities and functions of CMS are divided into four "programs," which, in addition to the CLIA program, include Medicare, Medicaid, and the State Children's Health Insurance Programs (SCHIP). CMS performs its field operations through regional offices, which also serve as the liaisons with state and local agencies.[27] Through its Center for Medicaid and State Operations (CMSO), CMS also partners with state and local governments to manage CMS programs. In terms of CLIA, this partnership is most evident in functions that relate to compliance oversight, in particular, the performance of clinical laboratory inspections or surveys by state survey agencies.[28] Individual states may apply to be deemed as "exempt" under CLIA. When exempted, the state takes on the burden of clinical laboratory regulation. At the time of this writing, there are only two CLIA exempt states: Washington and New York.

The Regulatory Code and Regulated Entities

The regulations that pertain to clinical laboratory testing are codified in Title 42 of the CFR. CLIA defines a laboratory as "any facility that performs laboratory testing on

specimens for the diagnosis, prevention, treatment of disease, or impairment of, or assessment of health."[25] All laboratories that perform even a single test on human specimens for these purposes, even those entities that do not bill to Medicare, are subject to federal regulation under CLIA and must register with the CLIA program.[25] The primary exception is a laboratory that performs testing for research purposes only. Thus, all laboratories within blood banking and transfusion services, except research laboratories, are regulated under CLIA.

Test Complexity and CLIA Certification

The applicability of specific CLIA regulations and the extent of regulatory oversight are based on the complexity of the test(s) performed by the clinical laboratory. Based on the technical demands of a test and the expertise required for the performance of a test, a test method is placed into one of the following categories: waived complexity, moderate complexity, or high complexity.[26] For each moderate- and high-complexity test, CLIA outlines requirements for quality control, quality assurance, personnel qualifications, proficiency testing, and patient sample and result management. CLIA does not specify such requirements for waived tests, for example, a point-of-care rapid diagnostic test for influenza performed in a physician's office. Although required to register with the CLIA program, clinical laboratories that perform only waived tests, also known as "waived laboratories," are only obligated to follow the test manufacturer's instructions.[30] Furthermore, these waived laboratories are not subject to routine inspections under CLIA.[31]

All clinical laboratories, even those that perform only waived tests, are required to apply to CMS for CLIA certification by submitting the "CLIA Application of Certification" (Form CMS-116) to the CMS-affiliated state agency in the state in which the clinical laboratory resides.[32] The application review focuses on the assessment of the complexity of test(s) performed by the clinical laboratory, the determination of the type of certificate to be issued, and the establishment of fees to be collected. The types of CLIA certificates are listed in Table 15–4. As a "user fee–funded" government program, all costs that relate to CLIA compliance, including registration, certification, and inspection fees, are required to be covered by the regulated laboratory.

Compliance Oversight

To ensure compliance with CLIA regulations, clinical laboratories that perform moderate- and/or high-complexity tests are obligated to submit to routine performance surveys. CMS follows an "outcome-oriented survey process," which focuses on assessing the overall quality of laboratory performance and not on an in-depth evaluation of each specific regulatory requirement.[33] The survey is typically an on-site inspection of the clinical laboratory; however, if the laboratory has shown consistently good performance, the survey can be in the form of a self-assessment, known as an *Alternate Quality Assessment Survey* (AQAS),[34] which does not require an on site inspection. Surveys are performed by the survey agency in the state in which the clinical laboratory resides or, in some cases, by the CMS regional office.

If a clinical laboratory fails to comply with regulations, maintains operations that pose an immediate threat to public welfare, and/or fails to show improvement in test performance deficiencies, then CMS is obligated under CLIA to proceed with enforcement actions. These enforcement actions include, but are not limited to, on-site monitoring of the laboratory by the state, mandatory retraining and technical assistance, civil penalties (fines), suspension or revocation of CLIA certification, suspension of Medicare/Medicaid payments, cancellation of Medicare/Medicaid approval, and court order of injunction to refrain from violative operations or practices.[35]

SUMMARY

In summary, regulation is a government's authority over a nongovernment body's operations and processes for the general intention of protecting public health and welfare. Compliance with regulations, which are the legal requirements established through the enactment of legislation, is nonvoluntary, and failure to comply with regulations is justification for civil and/or criminal action. Blood banks and transfusion services in the United States are subject to regulatory oversight by a variety of government agencies, with specific regulatory influence from the FDA for blood and blood manufacturing and the CMS for clinical laboratory performance. Regulations are codified in the CFR and organized into Titles according to the specific regulatory agency. Given that regulatory code is continuously updated, to ensure compliance, regulated entities must remain up-to-date on regulations and changes to regulatory code. Lastly, because the area of regulation is closely linked to the areas of accreditation and quality standards (Chapter 16) and legal practices (Chapter 17), a review of these subjects provides a more comprehensive view of regulation in the context of blood banking and transfusion practice.

Table 15–4 **Types of CLIA Certificates**

Certificate of Waiver. This certificate is issued to a laboratory to perform only waived tests.
Certificate for Provider-Performed Microscopy Procedures (PPMP). This certificate is issued to a laboratory in which a physician, midlevel practitioner, or dentist performs no tests other than the microscopy procedures. This certificate permits the laboratory to also perform waived tests.
Certificate of Registration. This is a certificate issued to a laboratory that enables it to conduct moderate- or high-complexity laboratory testing, or both, until it is determined by survey to be in compliance with the CLIA regulations.
Certificate of Compliance. This certificate is issued to a laboratory after an inspection that finds the laboratory is in compliance with all applicable CLIA requirements.
Certificate of Accreditation. This is a certificate that is issued to a laboratory on the basis of the laboratory's accreditation by an accreditation organization approved by HCFA.

Chapter 16

Quality Assurance, Control and Improvement, and Accreditation

Richard J. Benjamin

INTRODUCTION

Quality, "a degree of excellence" or "superiority of kind,"[1] is difficult to define objectively, and thus it is often viewed differently by patients, regulatory agencies, and accrediting bodies. Consequently, blood bank professionals are held to quality standards set by a variety of agencies that have different foci. For example, the Food and Drug Administration (FDA), as a federal regulatory body, concentrates on the quality of the end product and applies pharmaceutical industry–type standards to the collection, testing, and provision of safe blood. In contrast, the Joint Commission for Accreditation of Healthcare Organizations (JCAHO), an independent, not-for-profit accrediting body, focuses primarily on quality of patient care and examines aspects of the hospital transfusion service involved with ordering, processing, and transfusion of blood. These complementary and overlapping approaches to ensuring quality have led to the need for transfusion services to maintain sophisticated programs in order to comply with the variety of state, federal, and industry regulations and standards.

QUALITY OVERSIGHT: REGULATION AND ACCREDITATION

Background

The general purpose of blood establishment regulation and accreditation is to guarantee safe, effective blood products and to ensure high-quality care of patients. Although similar in the overall promotion of quality, *regulation* and *accreditation* are distinct in terms of the structure for quality oversight and compliance enforcement. *Regulation* implies the enactment and enforcement by the government of laws and rules for required industry practices. If a regulated entity fails to comply with a regulation or, in other words, breaks a law, the potential consequences are civil or criminal penalties. *Accreditation*, conversely, involves a process by which an establishment demonstrates compliance with standards set by a nongovernmental professional or industry-related body. If compliance is not demonstrated, accreditation may not be granted or may be revoked; however, legal penalties cannot be applied for noncompliance with standards of an accrediting agency. Although technically distinct, in practice, regulation and accreditation often overlap. For example, accrediting standards are often viewed as standards of practice and may be invoked in a court of law as evidence for compliance with or deviation from accepted practice. In addition, accrediting agencies often incorporate government regulations into industry standards, and accreditation may serve as support for quality compliance in a government assessment of a regulated establishment. Finally, accrediting agencies can have influence on regulatory legislation through associated political action committees, industry testimony, and scientific panels.

Regulation of Blood Establishments

From a federal regulatory standpoint, blood products are viewed as both drugs and biologics.[2] Under the provisions of the Federal Food Drug and Cosmetic Act (FDC) of 1938 and the Public Health Service (PHS) Act of 1944, blood establishments are subject to federal regulations for registration, licensing, and inspection.[3] In 1972, the FDA was granted responsibility for regulatory oversight and enforcement of the blood industry, with the authority to inspect both licensed and unlicensed blood establishments. To ensure uniform blood component production throughout the United States, in 1975, the FDA issued Current Good Manufacturing Practices (cGMPs) that specifically focus on the blood industry.[4]

As defined in the Title 21 of the Code of Federal Regulations (CFR) Part 607.3, a blood establishment "means a place of business under one management at one general physical location" and includes, but is not limited to, blood banks, human blood and plasma donor (collection) centers, component preparation facilities, and hospital transfusion services. A blood establishment that enters into human blood and blood component manufacturing, which includes collection, preparation, and processing, must register with and submit to the FDA a list of all products for commercial distribution within 5 days of initiating operations. In addition, once registered and engaged in manufacturing operations, the blood establishment is required to register annually and submit an updated list of manufactured products.[5] Prior to engaging in interstate transport of blood or blood components, under Section 351 of the PHS Act, a registered blood establishment is further required to file a biologics license application (BLA), which includes a prelicense inspection by the FDA's Center for Biologics Evaluation and Research (CBER). Prior to December 1999, blood establishments were required to submit a separate establishment license application (ELA)

and a product license application (PLA); however, in accordance with the FDA Modernization Act of 1997 (FDAMA), the ELA and PLA are now consolidated into a single BLA. To ensure that manufactured blood or blood components are safe, effective, free of adulteration, and appropriately labeled, the FDA's Office of Regulatory Affairs (ORA) performs routine announced or unannounced inspections of registered and licensed blood establishments. In addition to blood and blood component manufacturers, the FDA has recently extended its regulatory oversight to facilities that manufacture cellular and tissue-based therapeutics, including hematopoietic stem cells derived from blood, umbilical cord blood, and bone marrow.[6]

A blood establishment is considered exempt from registration with the FDA if it does not collect autologous or allogeneic blood and does not perform procedures that the FDA considers consistent with whole blood or component processing. An exempt hospital blood establishment, referred to as a "hospital transfusion service," may perform unit crossmatch, pool cryoprecipitate or platelet units, thaw frozen units, prepare recovered plasma, or transfuse blood components without being required to register. If the blood establishment performs prestorage leukoreduction, cell washing, or irradiation of blood or blood components, then the establishment is required to register with the FDA. In 1980, in accordance with a Memorandum of Understanding (MOU), the FDA transferred the responsibility for inspection of exempt transfusion services in hospitals approved for Medicare reimbursement to the Health Care Financing Administration (now called the Center for Medicaid and Medicare Services [CMS]).[7] Although CMS performs routine surveys of exempt hospital transfusion services, the FDA reserves the right to inspect these blood establishments, if required. For more information about federal regulation of blood manufacturing, the reader is referred to Chapters 12 and 15.

In addition to FDA regulatory oversight of blood manufacturing operations, blood banks, and transfusion services that test blood (e.g., ABO and Rh typing, antibody screening and identification) are subject to the Clinical Laboratory Improvement Amendments of 1988 (CLIA 1988),[8,9] which set standards for good laboratory practices. Responsibility for ensuring compliance with CLIA is assigned to the CMS. This compliance monitoring is achieved during triennial inspections by JCAHO, an accrediting agency with deemed status from the CMS. Finally, in many states in the United States, blood banks and transfusion services are subject to state regulations, which may include requirements for registration and annual reporting of adverse transfusion events. Requirements for reporting and inspections vary from state to state.

Accreditation of Blood Establishments

Professional societies and accrediting bodies such as AABB,[10] the College of American Pathologists (CAP),[11] and the Foundation for Accreditation of Hematopoietic Cell Therapy (FACT)[12] publish lists of voluntary standards to which many institutions subscribe. Regular inspections are undertaken to ensure compliance. These voluntary standards are intended to allow the profession to inspect and regulate its own practices outside the punitive environment of federal and state regulation. Accreditation by these agencies has yet to preclude inspection by the FDA or JCAHO.

AABB accreditation is based on the demonstration, through regular inspections, that the service has a detailed quality system under executive management, with written policies, processes, and procedures to cover the following: personnel qualification, training, competence, and proficiency; equipment qualification and validation; supplier qualification and vetting; appropriate process controls; secure and retained documents and records; internal and external assessments and audits; investigation of deviations, nonconformances and adverse events; process improvement through corrective and preventive action; and safe and adequate facilities. Similarly, CAP publishes a checklist of requirements for accreditation of all clinical laboratories, including the transfusion service. CAP accreditation is frequently used by smaller, non-FDA–registered facilities to demonstrate quality and compliance.

QUALITY ASSURANCE IN THE HOSPITAL AND THE ROLE OF THE TRANSFUSION COMMITTEE

Hospital transfusion practice is one focus of the JCAHO regulatory effort to ensure the quality of care, services, and treatment provided to patients. JCAHO standards and surveys form not only the basis for triennial inspections but also provide a framework for continuous operational improvement as hospitals incorporate guidelines into everyday practice.[13] Hospitals are required to have in place systems to collect data and monitor their performance, with blood and blood product use specifically mentioned as key parameters. Hemolytic transfusion reactions, in particular, are identified as sentinel events that should be reported and that should be subject to root cause analysis and formulation of an action plan. These requirements may be met by instituting systems for reviewing blood use, including: (1) ordering; (2) distribution, handling, and dispensing; (3) administration; and (4) the effects of transfusion. Oversight of these reviews is the responsibility of a hospital transfusion committee, or its equivalent, composed of members from departments that use blood, clinical laboratories, blood bank, nursing, and administration.[14,15] In this view, transfusion is a cooperative effort that requires quality assessment and documented improvement exercises that are performed continuously and according to objective guidelines used to monitor performance. Specific aspects that may be subject to audit and review include the adequacy of the blood supply, the use and wastage of autologous blood, mislabeling of patient specimens, turnaround time for completing immediate and routine transfusion orders, and the documentation of patient identification and vital signs at the time of transfusion. Further important aspects are investigations of transfusion reactions, appropriateness of blood orders, use of intraoperative blood salvage equipment, and use and maintenance of blood warmers.

Transfusion practice guidelines and criteria for specific product use vary between institutions and are developed by the transfusion committee with reference to criteria published in peer-reviewed journals. Examples are shown in Table 16–1. Such practice guidelines are not intended to serve as medical indications for transfusion; rather, they set limits outside of which the ordering physician should be required

Table 16–1 Examples of Criteria for Blood Component Administration in Adults

Red Blood Cells
Symptomatic anemia in a normovolemic patient
Acute loss of >15% of blood volume or evidence of inadequate O_2 delivery
Hematocrit <24% in a chronically transfused patient
Hematocrit <27% in a patient with severe cardiac or pulmonary dysfunction
Platelets
Platelet count <10,000/μL in a stable patient without bleeding risk factors
Platelet count <20,000/μL in a stable patient with risk factors for bleeding
Platelet count <50,000/μL for impending surgery or invasive procedure
Bleeding in patient with qualitative platelet defect, regardless of cause
Fresh Frozen Plasma
PT and/or PTT >1.5 normal value in patient undergoing surgery, an invasive procedure, or active bleeding
To reverse coumadin overdose in a bleeding patient
Bleeding after transfusion of more than one blood volume or signs of disseminated intravascular coagulation
For plasma exchange in patients with thrombotic thrombocytopenic purpura
Cryoprecipitate
Prevention or treatment of bleeding in patients with dysfibrinogenemia
Prevention or treatment of bleeding in patients with fibrinogen <100 mg/dL

to provide additional justification. Review of appropriateness of blood use is an important function of the transfusion committee, and there is a requirement that 5% of all transfusions be audited on a quarterly basis. Review may take one of three forms:

1. *Prospective review* is the process by which a blood bank designee evaluates the indication for transfusion at the time of the transfusion order. If the criteria for appropriate component use are met, the components are released. If not, the physician is asked to provide further justification for the specific order. If transfusion is urgent, however, the blood product may be released and the follow-up information obtained retrospectively.
2. *Concurrent review* requires transfusions to be assessed within 24 hours of issue, typically while the patient is still in the hospital and the indications are still fresh in the memory of the ordering physician. Both concurrent and prospective reviews provide opportunities to educate medical staff with respect to appropriate use of transfusions.
3. *Retrospective review* is undertaken more than 24 hours after transfusion. This type of review may be less effective. Trends in transfusion practice may be documented, although less educational benefit may be gained.

Overall, the purpose of blood use review is to provide opportunities to identify areas that need quality improvement. The emphasis is as much on ensuring that blood is available and used when it is needed as it is on preventing waste of a limited resource and unnecessary exposure of patients to the risks of transfusion.

QUALITY ASSURANCE IN THE COLLECTION AND MANUFACTURE OF BLOOD PRODUCTS

Blood components are considered drugs by the FDA because their use is meant to produce therapeutic benefit for the patient.[16] Establishments that collect blood (even autologous products) are viewed as pharmaceutical manufacturers. This approach raises significant practical issues. The principles of cGMP for drugs, as described in 21 CFR Parts 210 and 211,[17] are based on the concepts of continuous process control and lot release of products. In this view, blood donors are analogous to sources of raw material, and donor testing is simply quality control of incoming supplies. Furthermore, each blood product is a unique lot and therefore requires individual lot release, whereas with drugs, a batch of drug may be released. With blood products, quality control of each lot is not usually feasible. For this reason, more emphasis is placed on quality assurance of overall processes rather than on testing each product for quality parameters, such as volume, weight, hematocrit, and leukocyte content. The FDA clearly recognizes the unique nature of blood products as both blood and biologics and has promulgated a second series of regulations in 21 CFR Parts 600 to 680 that are specific for blood[4] and complement those in 21 CFR 210 and 211. The underlying principle of regulatory control of blood products is that by enforcing strict quality assurance of manufacturing processes, the statutory agencies hope to ensure the quality of individual blood products. Nevertheless, the advances in the field of blood safety, including the development of new tests (e.g., nucleic acid testing) and processes (e.g., leukoreduction), outstrip the ability of the federal government to promulgate law. Consequently, the industry relies on a series of guidelines and notices from the FDA that supplement the CFR and create many standards for the industry.

The Principles of cGMP

The concept of cGMPs is founded on the need to demonstrate control of all aspects of a manufacturing process, with documentation of all variables. This control should allow any single product to be tracked from donor to recipient and all reagents, facilities, and personnel to be traced so that any deviations may be fully identified, investigated, and rectified. Tight control of the manufacturing process, combined with suitable in-process quality control procedures and regular quality assurance exercises, serve to ensure the potency, efficacy, and purity of the final product.

The statutes promulgated in 21 CFR 211[17] and 21 CFR 606[4] cover all aspects of manufacturing, including personnel; buildings and facilities; equipment; components and containers; packaging; labeling; storage; holding and distribution; records; production and process controls; and salvaged products. Central to this regulatory structure is the need to document all procedures in standards of practice (SOP) and to qualify all facilities, equipment, and components by validation before use. A key role is ascribed to the quality control unit, which has overall responsibility for the release of final products.

Continuous Quality Improvement

Continuous quality improvement (CQI) is based on the premise that, despite the utmost care, processes and systems

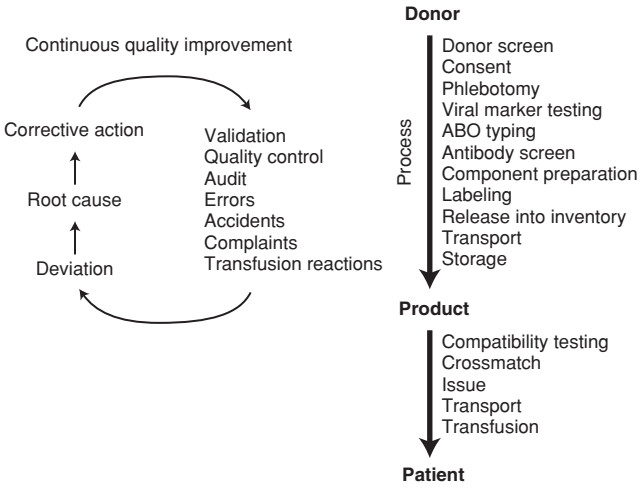

Figure 16–1 Continuous quality improvement.

cannot be designed to be perfect. It is therefore necessary to implement an evolutionary refining process to detect deviations and to put in place appropriate corrective actions (Fig. 16–1). The FDA requires that blood establishments have in place procedures for thoroughly searching for signs of deviations in processes. These deviations may become apparent during validation of a new process, during quality control (QC) and quality assurance (QA) audits, or through occurrences such as errors, accidents, complaints, and transfusion reactions. Establishments must have systems in place to investigate deviations, to determine their root cause, and to put in place corrective action. Central to this concept is the idea that staff and customers must be encouraged to report deviations; indeed, they should be encouraged to search actively for mistakes without fear of retribution. This view recognizes deviations as opportunities to improve and to provide better services. Well-designed processes performed by well-trained staff should ideally not allow deviations. When they occur, it is critical to thoroughly evaluate the problem and the involved processes to ensure systemic quality improvement.

The Role of the Quality Assurance Unit

Ensuring the safety of blood products requires the implementation of effective control over manufacturing processes and systems. In 1995 the FDA published guidelines that require blood establishments to develop written QA programs with an emphasis on error prevention rather than on retrospective detection.[18] QA is the sum of activities planned and performed to provide confidence that all systems and their elements that influence the quality of a product are functioning as expected and can be relied on. QA functions include QC procedures and audits, as well as ensuring that standards are in place for facilities, personnel, procedures, equipment, testing, and record keeping.

All blood establishments are required to have a QA function, either as a QA unit in large establishments or a single individual in small transfusion services. Whatever the size, the QA unit is required to be separate from the management of production and to report directly to the responsible head or the designated qualified person in charge of the operation. The QA unit has final responsibility for the quality of products released and must have the power to stop production and release of product if it deems necessary.

Major responsibilities of the QA unit include the following:

1. *Standard operating procedures.* Development of written procedures is a fundamental component of cGMP that promotes an environment with minimal variation. Ensuring that SOPs exist and that they accurately describe each procedure is a basic function of the QA unit. Each SOP must be reviewed, signed, and indexed in a master copy of the SOPs. SOPs must be available to employees who perform the tasks. SOPs must be updated promptly to reflect changes in processes, and these modifications must be appropriately documented. SOPs must exist for QA unit activities that define its role in reviewing, approving, and authorizing all SOPs.
2. *Training and education.* The QA unit should assist in developing, reviewing, and approving training and educational programs for all personnel. This responsibility includes new employee orientation; cGMP, SOP, and QA training; and technical, supervisory, managerial, and computer system training. The QA unit is ultimately responsible for ensuring that personnel are appropriately qualified and trained to perform their tasks. Written documentation of training must be on file.
3. *Competence evaluation.* The QA unit should implement a formal, regular competence evaluation program to ensure that staff maintain the skills to perform their tasks. This program should include direct observation of performance of routine and QC procedures, review of worksheets, preventive maintenance records, and written tests to assess theory and knowledge of SOPs. Remedial action and retraining should be documented in the personnel records.
4. *Proficiency testing.* The QA unit should review and monitor proficiency testing procedures and results to ensure adequate evaluation of test methods, equipment, and personnel competence. Proficiency testing should be performed by the same personnel who perform the tasks routinely and should include backup or alternative testing (e.g., manual procedures performed during computer downtime). There should also be a written plan for remedial action in the case of unsuccessful proficiency testing performance.
5. *Validation.* The QA unit is responsible for ensuring that validation protocols are designed prospectively, performed, and evaluated, and that written validation reports are prepared. Although validation of test methods is a standard practice in the clinical laboratory, the extension of these principles to manufacturing processes, computer systems, and facilities poses unique challenges. Validation requires documented evidence to demonstrate that the system is performing as designed and with the expected degree of accuracy and reproducibility. Complaints, errors, accidents, and problems at critical control points should be reviewed to determine the need for revalidation, according to the FDA's *Guideline on General Principles of Process Validation.*[19]
6. *Equipment and computers.* Equipment, in particular, should undergo installation qualification by the establishment (not the manufacturer). This is a form of validation that establishes "confidence that process equipment and ancillary systems are capable of consistently operating within established limits and tolerances." There should be written procedures for equipment qualification,

validation, maintenance, calibration, and monitoring. A major piece of equipment that is easily overlooked in the blood bank is the computer-based information system. The FDA has recognized that computers play a central role in practically all blood bank processes and that the risk of deviation caused by computer errors is high. For this reason, blood bank information systems are considered medical devices in their own right and are directly regulated by the Center for Biologics Evaluation and Research (CBER) at the FDA, requiring 510(k) approval before being marketed. This requirement places a unique burden on the manufacturers of blood bank software to demonstrate good software engineering practices and to document and validate all aspects of their systems.

Furthermore, blood establishments are required to validate all aspects of software on-site, an exhaustive process that was initially described in an FDA draft guidance, although a finalized guidance document had not yet been issued at the time of this writing.[20] As with other processes in the blood bank, there must be a system in place to document complaints and problems with computer software and hardware, with documented investigation, root cause analysis, and corrective actions. New versions of software require revalidation. Many institutions find that they require a dedicated computer person to perform these tasks despite the purchase of commercial software systems. The situation for homegrown computer programs has been less clear historically, as these programs are not for commercial sale. Homegrown systems may be used without preapproval, but the FDA has made it clear that they expect the same standards to apply to homegrown computer system design as to commercial vendors. Although FDA authorities do not routinely inspect the manufacturers of homegrown systems, they enforce the full weight of the law should major deficiencies in the computer system become apparent during routine blood bank inspection.

7. *Error/accident reports, complaints, and adverse reactions.* Licensed establishments are required to report to CBER all errors and accidents that affect the safety, quality, identity, potency, or purity ("SQuIPP") of a blood product. The FDA has announced that nonlicensed establishments, including hospital transfusion services, must report similar occurrences, now termed *biological product deviations* (BPDs), if the product has left the control of the establishment by the time the occurrence is detected.[21] It is the role of the QA unit to investigate all complaints, errors, and accidents to determine whether there is a need to report each occurrence. Similarly, all adverse reactions must be fully investigated and documented, and recalls and withdrawals must be handled according to established procedures. In particular, transfusion reactions must be fully investigated, and in cases of suspected bacterial contamination, a full review of manufacturing procedures must be undertaken. Fatalities that are related to either the donation process or the receipt of blood products are reportable within 24 hours to a special hotline at the FDA. This reporting must be followed within a week by a full written report describing the occurrence and its subsequent investigation. This written report, in turn, usually triggers a focused FDA inspection.

   As outlined earlier, an essential element of CQI is feedback into the QA system of knowledge acquired through investigation of complaints, errors, accidents, or adverse reactions. This is seen as a vital source of information on which continuous quality improvement efforts can be focused through a system of corrective actions and fine-tuning of existing processes.
8. *Records management.* The QA unit is responsible for ensuring that all records, including computer records, are adequately stored and held for the appropriate periods as defined by the FDA. Systems of storage, especially computerized systems, must be fully validated and reviewed as necessary to ensure completeness.
9. *Lot release procedures.* Each component released by a blood establishment represents one lot of product and bears a lot number, usually the unit number assigned at the time of collection. QA procedures must ensure that all records pertaining to manufacture are reviewed for accuracy, completeness, and compliance with existing standards before release. A second person should review the significant steps. Labeling procedures, especially, are considered critical control points and must be tightly controlled.
10. *QA audits.* A QA audit is one mechanism for evaluating the effectiveness of the total quality system. Comprehensive audits should be conducted periodically in accordance with written procedures and should consist of a review of a statistically significant number of records. On occasion, focused audits may be conducted when quality problems have been identified or to monitor a particular critical control point. Individuals conducting audits must have sufficient knowledge of and expertise in the process under review but must not be responsible for the processes being audited. There should be a written report documenting audit procedures and results; this written report should include a review by the responsible head or other designated qualified person to evaluate the results of the audit so that suitable corrective action can be implemented. QA audits should be constructed using a systems approach and may include review of donor suitability, blood collection, manufacturing, product testing, storage and distribution, lot release, and computers. QA audits should evaluate critical control points and key elements in each system, and each establishment should customize its audits for its own systems.

RECALLS AND WITHDRAWALS: PRACTICAL APPLICATION OF THE CONCEPT OF SQuIPP

Continuous quality improvement exercises aim to use all sources of information to identify BPDs, with a view to improving processes and systems. In the endeavor to identify deviations, problematic products may be identified that have been released from inventory or even transfused, requiring a consideration of the safety of the recipient. If the deviation from the standard was the result of an error in the collection or processing of the unit by the collecting facility, in violation of the laws overseen and enforced by the FDA, especially violations of cGMPs, "and against which the agency would initiate legal action,"[22] the process is called a *biologic recall.* Recalls may be conducted voluntarily on a firm's own initiative, by FDA request, or by FDA order under statutory authority.[23] All recalls must also be reported to the FDA, regardless of who initiated the action. The FDA subsequently classifies recalls as follows: A *Class I* recall is a

situation in which there is a reasonable probability that the use of or exposure to a violative product will cause serious adverse health consequences or death. A *Class II* recall is a situation in which use of or exposure to a violative product may cause temporary or medically reversible adverse health consequences, or where the probability of serious adverse health consequences is remote. A *Class III* recall is a situation in which use of or exposure to a violative product is not likely to cause adverse health consequences.[22] These recalls are then reported publicly by the FDA several months later.[24] If large, multiunit recalls are excluded, the more common blood center recalls occur typically at an approximate rate of 1 in 5000 components distributed.[24]

A *market withdrawal* occurs when a product has a minor violation that would not be subject to FDA legal action (i.e., not an "actionable violation"). The firm removes the product from the market or corrects the violation. For example, a product removed from the market due to tampering, without evidence of manufacturing or distribution problems, would be a market withdrawal. For the blood center, withdrawals are most often triggered by information provided by a blood donor or a third party after donation that, if known at the time of donation, would have led to deferral of the donor. An example would be the withdrawal, in the late 1990s, of blood products that were obtained from donors at risk of Creutzfeldt-Jakob Disease (CJD), or variant CJD. The FDA became aware of a theoretical risk of transfusion transmission of these ailments and advised that previously collected, "in-date" products from donors at risk should be withdrawn. Likewise, in the fall of 2002, the discovery that West Nile virus could be transmitted by blood products led to the later, voluntary withdrawal of most frozen blood products from certain localities collected during the period of highest risk of transmission, on the grounds that they might be contaminated. These products met all the required standards of blood safety at the time of manufacture, but they were later considered unsafe and required withdrawal. Blood component–related market withdrawals occur with approximately the same frequency as recalls.[25]

In deciding whether postdistribution information warrants action on the part of a blood establishment, it is helpful to consider *SQuIPP* (Table 16–2). Any deviation from established procedures or deferral criteria that would lead to reduced *safety* in the product (i.e., greater potential for harmful effects) generally leads to withdrawal or recall. For instance, a presenting donor may state that he received a needlestick exposure to blood 4 months earlier, before a donation 3 months ago. Because donors with exposures to blood represent a group that may have a greater risk of carrying transfusion-transmissible disease, they are deferred. Had the center known of the blood exposure at the time of the earlier donation, the donor would have been deferred; therefore, components distributed from the donation 3 months ago must be withdrawn.

Quality represents conformance of a product or process with preestablished specifications or standards. If it is discovered after the release of a leukoreduced component that the leukoreduction quality control for that component failed, then the component must be recalled.

Identity indicates the need to ensure that the identification of the donor, the unit, and its components is certain throughout the collection, processing, and labeling steps. For instance, if a unit of red blood cells, acceptable in every other way, is stated on the label to be negative for Kell (K1) when it is not, the unit is "misbranded," and it could be harmful to a recipient whose serum contains anti-K1.

Purity deals with freedom from extraneous contaminating matter in a product. If, after a recipient febrile transfusion reaction, the residue from a unit of platelets is cultured and is found to contain microorganisms, the other components from that collection should be withdrawn, because they may also have been contaminated.

Potency represents the ability of a product to produce the desired effect. Here, loss of potency typically indicates a failure of quality control. The findings that fewer than 75% of platelets units have 5.5×10^{10} platelets and that red blood cell recovery after leukoreduction of red blood cells is less than the required amount represent a loss of potency. If these products had been distributed, discovery of their deficiencies would have led to a recall.

Table 16–2 **SQuIPP**

Use SQuIPP to help determine whether a product needs to be recalled or withdrawn
Safety: does the product have a greater potential than usual for harmful effects?
Quality: does the product conform to preestablished specifications or standards?
Identity: is the identity of the final product and its labeling certain?
Purity: is the product free of extraneous contaminating matter?
Potency: can the product produce the desired effect?

Actions Taken by the Blood Center

When the collecting facility discovers that a product that does not meet SQuIPP criteria has been released, staff members must work rapidly to notify the receiving transfusion service. For in-date products that may still be in the hospital inventory, this notification is done typically by telephone, to allow immediate quarantine of the suspect product, followed by written notification. The center must also quarantine any in-date products in its inventory. Because the information is typically obtained at the time of a subsequent attempted donation, platelet and red blood cell components are usually outdated, but frozen plasma, frozen red blood cells, and cryoprecipitate may still be in the center or hospital inventory. The center in-date inventory must be identified and quarantined quickly. Hospitals must be notified of in-date components as soon as possible, with written notification following soon afterward. When the hospital returns suspect components, the center usually destroys them or corrects the underlying problem with appropriate documentation. If the postdonation information would lead to donor deferral in the future, the center must place the donor in the deferral registry and must notify the donor of this action, to prevent collection and distribution of any future donations. The center must document its actions and must seek from the consignee information regarding the final disposition of components.

Actions Taken by the Hospital Transfusion Service

When notified that products are being recalled or withdrawn, the hospital must act immediately to quarantine any

such products in the inventory. The hospital must ensure that proper steps are taken and documented. When products have been transfused (75% of recalls in one hospital were found to be for components already transfused),[25] the hospital transfusion service must consider carefully the appropriate steps to take, in concert with hospital administration and risk management staff. For some recalls or withdrawals, no further action may be necessary. For instance, when a unit that was incorrectly labeled as K1 negative was subsequently transfused to a recipient who had no anti-K1, no clinician or patient notification would be needed, merely a note for the record of the facts. For other situations, the transfusion service may wish to notify the clinician but advise him or her that patient notification is probably unnecessary. For instance, red blood cells from a donor who had traveled to a malarial area and that were transfused 6 months earlier would have caused transfusion-induced malaria within 50 days of transfusion, and if no febrile disease developed, these red blood cells would represent no additional risk.[26] Finally, in some cases, the patient should be notified, particularly when there is some risk of infectious disease transmission, so that investigation, counseling, and treatment can be considered. Patient notification may be required, for instance, for possible transmission of human immunodeficiency virus (HIV) or hepatitis C virus (HCV).[27] In each case in which a component has been transfused, the transfusion service must balance the evidence that an infectious agent was transmitted through transfusion, the potential benefit to the recipient of receiving this information, and the potential harm to the recipient when no diagnostic test exists that can resolve whether such transmission has occurred.[28] If the transfusion service physician finds the information sent to be insufficient, sometimes more information can be obtained from the blood center. Fortunately, most recall and market withdrawal notifications have little clinical significance.[25,29]

LOOKBACK

When a donor unit is found to be positive for an infectious disease marker, several actions must be taken by the collecting blood center. Obviously, the implicated unit must be destroyed, and this disposition must be recorded. In addition, donor-related actions are required (notification, counseling, and placement in a donor deferral registry), and action may need to be taken to ensure that previous units donated by that donor have not transmitted disease. The latter process is termed *lookback*.

When determining the risk of transfusion transmission of disease, prevalence, measured for transfusion-transmitted diseases by an infectious disease marker, is usually of less concern than *incidence,* or the new acquisition and development of disease, because blood with a marker indicating prevalence is usually readily identified by testing and is discarded. For a newly acquired, incident viral agent, the concern is about transmission of disease during the *window period*, defined as the time between donor infection and the appearance of detectable markers of disease, a time in which current tests may not identify an infectious unit. The window period may be conveniently divided into two parts: an eclipse period, when the agent is undergoing proliferation in host tissue but is not present in sufficient numbers in the blood to be infectious,[30] and the subsequent infectious period, when circulating virus can be transmitted by the blood. The goal of test improvement has been to increase sensitivity to the extent that the infectious window period is reduced as much as possible. Because an infectious window period still exists, and may have been longer in the past, when a donor is found to have a newly acquired marker of an infectious disease, the more recent, previously seronegative donations of that donor must be regarded as suspect.[31] The risk of a previous donation's ability to transmit disease depends on the incidence of the disease and on the length of the infectious window period, the latter a function of the sensitivity of the test used. For HIV or HCV, using nucleic acid amplification testing, the infectious window period may be a few days, at most.[30] Notification of recipients of previously donated seronegative units is important, so that the recipients may be tested and, if they are positive for the agent, counseled and treated appropriately.

Actions by the Center and the Hospital

The blood center must identify previously donated units at risk from the implicated donor and must determine the components made from these units and the consignees to whom these components were shipped. The center must then notify the hospital of the situation and must obtain information about the final disposition of the components. If in-date components from such units may be available, the consignee should be notified as soon as possible after the detection of a repeat reactive screening test.

The specifics of the actions required vary by disease. For HIV and human T-cell leukemia/lymphoma virus (HTLV), the center searches for the first seronegative (or untested) unit previously donated and for all units donated for at least 1 year before that donation.[27] The center must identify all components made from the suspect units and must determine where they were sent. If any in-date components exist, these must be identified and quarantined if they are in the center. If these components have been distributed, the consignees of such components should be notified within a few days of the positive test result. The hospital, in turn, must ensure that the patient is notified (typically through the clinician, but if necessary, by the hospital directly) within a few weeks. For HIV, even if the patient is deceased, the patient's next of kin must be notified.[27] For HTLV, in contrast, the clinician can make the decision not to notify the patient or the recipient, if the decision is warranted clinically. Both the center and the hospital must document notification attempts.

For HCV lookback on a donor found to be seropositive, the same process is used. The center must identify units 12 months before the last seronegative unit, locate the consignees of components made from those units and shipped to the consignee, and notify the consignee within 45 days of the repeat reactive donation. The consignee must ensure that the patient is notified of the need for HCV testing and of the availability of testing and counseling. There must be documentation of three attempts to notify the recipient within 12 weeks of notification by the center.[32]

A massive retrospective HCV lookback of units donated between 1990 and 1999, on which lookback had not already been performed, was begun in 1999 and was completed by 2001. This *targeted* (identification of specific blood recipients) lookback process may not be very cost effective. One estimate is that of approximately 300,000 recipients to be notified, perhaps only 5000 to 10,000 will be living and will have newly recognized infections, and 1500 will ben-

efit from therapy.[33] Interim data from the U.S. Centers for Disease Control and Prevention corroborate these numbers and indicate that approximately 0.5% of recipients will be found to have newly recognized infections.[34] Despite the inefficiency of the targeted lookback process, no compelling evidence indicates that general notification of all blood recipients would be effective[35]; indeed, many of those recipients identified by targeted lookback would not otherwise be identified and treated.

CONCLUSION

Quality management in transfusion medicine is a formalized process that is required by law. Over the past 2 decades, blood establishments have focused on regulatory compliance in order to meet the standards of accreditation set by multiple agencies. These regulatory pressures have engendered a change in mind-set that is now increasingly pervasive throughout the industry: Quality accepts only the best and works hard to improve, despite cost constraints, shortages in the skilled workforce, evolving technology, and a growing regulatory burden. Quality is the ultimate goal, and compliance is merely obeying the rules. It is now clear that, along with refinements in donor screening and viral marker testing, the implementation of Quality and cGMP principles and improved clinical practice are responsible for the safety revolution that continues in blood transfusion.

Chapter 17

Legal Principles and Issues Central to Transfusion Medicine

Karen Shoos Lipton • Diane Killion

Today's transfusion medicine and cellular therapy professionals are challenged with striking an appropriate balance between optimizing and maintaining the safety of blood donors and recipients and effectively managing the legal risks inherent in the operation of blood-collection and blood-transfusion facilities. This chapter provides health care professionals with an overview of the growing number of legal issues that affect the transfusion medicine and cellular therapy communities and offers suggestions as to how to mitigate the associated risks in order to better serve donors and patients.

Because of the evolution of the law in these areas, more cases relate to the collection and transfusion of blood and blood components than to the collection, processing, storage, and administration of cellular therapy products. For this reason, this chapter focuses on cases relating to the transfusion of blood and blood components. As a practical matter, however, many of the legal issues that have affected transfusion medicine will similarly affect the cellular therapies field. Although the cases discussed in this chapter are intended to be illustrative of legal concepts, they are not intended to replace the advice of competent legal counsel.

LEGAL RISKS IN TRANSFUSION MEDICINE

Theories of Liability

A plaintiff complaining that he or she was wrongly injured by a transfusion typically looks to include the greatest number of defendants, based on as many causes of action as possible. For example, defendants may include clinician(s) who transfused blood and treated the patient, the hospital where the transfusion and treatment were provided, the blood center that collected the blood, and possibly the organization that set the applicable standards.

The claims may include failure properly to warn of the risks of treatment or surgery, failure adequately to discuss alternatives to transfusion such as autologous or directed donation, failure adequately to warn of the potential risks inherent in transfusion, negligent hiring and supervision of staff, failure adequately to test the donor for transfusion-transmitted disease, failure to develop or implement an appropriate "lookback" program for notifying recipients of infected blood, negligent standard setting, failure to transfuse at the proper rate, and negligently administering transfusions that were not medically necessary.

These causes of action are generally based on at least three different theories of liability: (1) negligence, (2) strict liability, and (3) breach of implied warranty. Appreciating the distinctions among the applicable theories is important to minimize the risk of liability.

NEGLIGENCE

Although the law of negligence varies significantly from state to state, the basic elements of a negligence claim are as follows: the defendant owed a duty of care to the plaintiff; the defendant breached the duty; the plaintiff's injury was directly or proximately caused by the breach; and the plaintiff suffered damages as a result.[1] In short, the theory of negligence holds that the provider of medical services is responsible for providing safe products and services that will not harm the patient and that are consistent with the prevailing standards of care.

Historically, negligence was grounded in fault-based liability: the negligent actions had to be proven to cause the injury. Beginning with the Restatement (Second) of Torts §402A (1964), a new basis for liability was widely adopted largely to hold manufacturers accountable for poorly designed products. This was termed *strict liability* or *liability without fault*.[2] To find a manufacturer strictly liable, one need prove only that the injury was due to the product's design, regardless of whether the manufacturer was at fault. The impetus for the adoption of the theory was to encourage manufacturers to make safer products by requiring them to absorb the real costs of the consequences of the unsafe product. However, recognizing that blood is a living tissue, inherently variable and incapable of being rendered uniform or completely safe, virtually every state has adopted special "Blood Shield Statutes" exempting blood from strict liability standards. Even in jurisdictions that have not yet adopted blood shield statutes, courts can decide that strict liability should not apply to blood collection and storage. A notable case is described in Box 17–1.

Elements of Negligence

Duty of Care

The first element in a successful negligence claim is establishing that the defendant owed a duty of care to the individual who is claiming harm. Traditionally, in cases involving the provision of health care services, a doctor-patient relationship between the defendant and plaintiff must be established

BOX 17–1 ***Illustrative Case***

Nestor v. Hospital Pavia[3] involved a patient who was transfused during August 2001 and was later diagnosed with hepatitis C. The patient alleged that both the local blood bank and the hospital were negligent as they provided contaminated blood and therefore were strictly liable for marketing a defective product, despite the performance of the most sensitive, specific, licensed, and unlicensed tests available at that time. The court decided to follow the vast majority of states with blood-shield statutes and determined that, as a matter of law, strict liability should not apply to blood collection and storage.

before a duty of care may be attached, although courts are not unanimous in defining the parameters of the duty of care. Courts in a few states, including Arizona, Maryland, Mississippi, Ohio, and Washington, have broadened the duty of care between physicians and patients to situations in which no traditional doctor-patient relationship exists.

One of the most striking cases illustrating this trend is *Stanley v. McCarver*[4] detailed in Box 17–2. Citing cases in the District of Columbia,[5] Michigan,[6] and New Jersey,[7] the Arizona Supreme Court noted that "[t]he requirement of a formalized relationship between the parties has been quietly eroding in several jurisdictions."[4] The court held that, in deciding whether a duty exists with no formal doctor-patient relationship, it is appropriate to consider "whether the doctor was in a unique position to prevent harm, the burden of preventing harm, whether the plaintiff relied upon the doctor's diagnosis or interpretation, the closeness of the connection between the defendant's conduct and the injury suffered, the degree of certainty the plaintiff has suffered or will suffer harm, the skill or reputation of the actors, and public policy."[4]

In the blood-transfusion setting, some courts have recognized a duty in even more attenuated relationships, such as between the blood provider and the recipient of the blood. Examples of this duty arise in "lookback" cases, which involve the notification of recipients of components from donors who have previously tested positive for an infectious agent. Once a blood collector becomes aware that one of its donors has a disease transmissible by blood transfusion, the provider has a duty to develop and implement an appropriate program to notify the recipient of any component that might transmit the disease. An important example of this attenuated level of relationship is described in Box 17–3.

In *Snyder v. AABB*,[9] a New Jersey court went to great lengths in finding that a duty of care existed between a standard setting organization (American Association of Blood Banks; [AABB]) and a plaintiff who had contracted human immunodeficiency virus (HIV) from a transfusion, even though no direct relationship was found between the parties. The court concluded that AABB owed a duty of care to an individual treated by one of its voluntary members because the association had voluntarily assumed responsibility for the nation's blood supply by inviting blood banks, hospitals, physicians, and the public to rely on its Standards. At the time of this writing, this logic has been adopted in only one other jurisdiction.[10]

In general, the majority of courts require some greater connection or relationship between the health care provider and the recipient of health care services. One court, refusing to impose liability on AABB as a standard setting organization, specifically recognized that "adverse consequences to the public by chilling scientific and medical debate on important issues and leaving these matters to the often slow and cumbersome processes of governmental agencies" significantly weighed against finding AABB liable under the circumstances presented.[11]

BOX 17–2 ***Illustrative Case***

In *Stanley v. McCarver*,[4] a nursing home contracted with a radiologist to read chest radiographs of prospective employees of the nursing home to screen for tuberculosis. The radiologist never met with the plaintiff but noted a spot on her chest radiograph and, in his report to the nursing home, recommended further evaluation. Although the nursing home's procedures called for notifying a prospective employee of radiographic results within 72 hours of receiving the report, the plaintiff was never notified of the defendant's report. Relatively soon thereafter, she was diagnosed with lung cancer and ultimately died a few years later.

BOX 17–3 ***Illustrative Case***

In *Smith v. American Red Cross*,[8] a blood-transfusion recipient who was infected by AIDS-contaminated blood in April 1984 and subsequently died, brought an action claiming, among other things, that the American Red Cross (Red Cross) did not promptly notify the recipient that the donor of the blood with which the recipient was transfused tested positive for human immunodeficiency virus (HIV). Rejecting a charge that Red Cross should have notified her immediately after the donor tested HIV positive in August 1985 instead of waiting until it developed its "lookback" program in July 1986, the court pointed out that the plaintiff had suffered no damages resulting from the delay because no allegation was made that the recipient spread the disease to anyone else, and, in 1985, no early-treatment protocols existed for those infected with HIV.

Breach

Once a plaintiff establishes the existence of a legal duty, the plaintiff must prove that the defendant breached the standard of care. The breach may be a failure to diagnose, a delay in diagnosis, improper treatment, a negligent rate of infusion, failure to obtain informed consent, and/or inferior care, including substandard surgery or any number of other purported acts of malfeasance. A review of transfusion-related case law reveals that courts apply three distinct standards of care: medical negligence, ordinary negligence, and professional negligence. Subtle but important differences exist among these standards, and the outcome of an individual lawsuit is often based on which standard is applied.

Medical Negligence: The standard of care applicable in a medical negligence action requires that a physician exercise the degree of knowledge and care ordinarily possessed and exercised by other members of the profession acting under similar conditions and circumstances. Expert testimony is generally required to establish medical negligence.

Ordinary Negligence: Ordinary negligence is a standard of care that can be assessed by a "reasonable man of ordinary prudence."[12] Thus, ordinary negligence cases do not require expert testimony. In general, plaintiffs prefer to frame their

cases as ordinary negligence actions rather than as medical negligence cases specifically to avoid the added burden of introducing expert testimony. This approach allows the defendant's actions to be judged by the finder of fact, often a jury, who measures the actions against what a reasonable person would do in similar circumstances. Very few cases involving donor screening or donor testing have been successfully asserted as a matter of simple negligence, although other blood center and transfusion service activities have been judged against the ordinary negligence standard.

Professional Negligence: In the blood banking and transfusion setting, most jurisdictions view the production and safeguarding of blood as a professional activity to be judged against the actions of a "reasonable professional" (the professional standard) as opposed to a reasonable person, as in ordinary negligence cases mentioned earlier. In its most traditional form, the professional standard requires that an expert offer testimony on the prevailing standard of care in the field. This evidence typically includes government regulations and applicable private standards and guidelines. Under this same standard, a single expert may not second-guess an entire profession.[13] Some courts, however, have broadened the evidence that can be introduced to establish the prevailing standard of care, including evidence about practices of other hospitals and transfusion services. This is most likely to occur in situations in which the standard of practice in the field is not settled. For most professional negligence cases, the less consensus that exists within the medical community concerning a specific course of action, the greater the opportunity for divergent outcomes in litigation.

Causation

The third element of negligence is establishing causation, in other words, determining that the defendant's breach of the duty of care was the actual or proximate cause of the plaintiff's injury.[14] In the transfusion setting, this means that the plaintiff must prove that it is more likely than not that the blood transfusion caused some form of injury, for example, HIV infection. Where the hospital, physician, or transfusion service can show that the plaintiff engaged in high-risk activities before the transfusion or that the particular morbidity or mortality could have been caused by a different source, it is more difficult to satisfy the element of causation.

When considering causation, the concept of foreseeability is relevant to determining whether certain actions or inactions constitute negligence. When the manner in which an injury occurs is so improbable or unpredictable that the defendant could not have "foreseen" it, the injury is not actionable. As cases discussed later in this chapter illustrate, the more foreseeable an untoward outcome is or was, the greater the potential exposure to liability.

Damages

The final element of negligence is proving that the plaintiff has suffered actual damages; a patient must have been injured as a result of the breach of the standard of care. The proper measure of damages is the amount that will compensate the plaintiff for the injury proximately caused by the defendant. These are called *compensatory damages* and are further subdivided into economic and noneconomic damages. Possible economic damages can include lost wages and medical expenses. Noneconomic damages are subjective and include pain and suffering, physical impairment, emotional harm, inconvenience, loss of society and companionship, and humiliation. In determining the amount of damages, it is appropriate to consider past, present, and future economic and noneconomic damages.

BOX 17–4 ***Illustrative Case***

In 2003, a New Jersey court awarded $300,000 in damages to a patient who, after a blood test for human immunodeficiency virus (HIV), was incorrectly informed by a doctor that he was HIV positive.[17] The patient brought a medical malpractice action against the doctor and hospital where the patient was treated, claiming that, as a result of the misdiagnosis, he became depressed and suffered from physical and psychological injuries. The court found that, although the hospital was not negligent, the doctor had deviated from the standard of care by failing to give the plaintiff pretest and posttest counseling, by misinterpreting the test results, by incorrectly advising the plaintiff that he was HIV positive, and by giving the results over the telephone rather than informing the plaintiff in person.

Plaintiffs sometimes claim that their fear of contracting a disease is a compensable injury.[15] These types of cases arose originally in the asbestos context, and plaintiffs have had mixed success expanding this cause of action into the transfusion arena. Pennsylvania, for example, does not allow monetary damages for an asymptomatic plaintiff's fear of contracting acquired immunodeficiency syndrome (AIDS) in the absence of actual exposure to the disease.[16] The opposite occurred in New Jersey, as described in Box 17–4.

CONTRACTUAL CAUSES OF ACTION: IMPLIED WARRANTY

Some plaintiffs apply a broad approach to litigation and sue not only on negligence theories, but also on theories founded in contract. Typically, such claims allege that the physician promised certain results from procedures or treatments, the patient is unsatisfied with the results, and the physician's failure to produce the promised results gives rise to an action for breach of contract or breach of warranty.

In one such case, a blood bank that supplied the wrong type of blood, resulting in a patient's death, was held not liable under the doctrine of implied warranty, because the transfused blood was not in any way unwholesome or defective.[18] The court reasoned that the patient's death resulted from the negligence of an employee who recorded the wrong blood-type number on the decedent's card. In the court's opinion, supplying blood for a fee constitutes the provision of a service, rather than the sale of a product and, accordingly, breach of warranty did not apply.

The best way to prevent breach of contract or breach of warranty claims is to avoid promising specific results; managing patient expectations is not only sound practice, but also can help to protect against certain causes of action.

DONOR SCREENING, DONOR TESTING, AND COMPONENT PROCESSING

In the field of transfusion medicine, most legal cases brought against blood centers, hospitals, and physicians involve challenges to donor-screening and infectious disease–testing practices. Although blood center and transfusion medicine professionals regard donor screening and, in particular,

donor questioning as relatively noninclusive and nonspecific for mitigating the risk of transfusion-transmitted disease, plaintiffs have often made this issue the focus of their complaints. In general, donor-screening complaints have centered around alleged "failures" in the donor-screening process, notably either the failure to ask a donor a specific question or a failure to rely on direct questioning to screen the donor for a particular risk.

Infectious disease–screening testing cases most often revolve around the failure to implement an available test, typically a test that is a "surrogate marker" for populations at risk for transmitting a specific agent but that does not directly identify the infectious agent. The period between the emergence of infectious disease and the development of a test for the agent responsible for transmission of the disease often presents the greatest risk of liability for a defendant. Additionally, in these same cases, the closer the injury is temporally to the implementation of testing for the agent, the greater the risk of liability. This concept is best illustrated by the early history of HIV and blood transfusion. The emergence of the first incidences of HIV related to blood transfusion occurred in 1981,[19] and the licensure of the first HIV test occurred on March 2, 1985.[20] This several-year period gave rise to a significant number of transfusion-transmitted (TT)-HIV cases aimed at standard-setting organizations, blood centers and hospitals, transfusion medicine professionals in both blood centers and hospitals, and clinicians involved in the patients' care. Courts have come to different conclusions about the liability of these parties for alleged deficiencies in donor screening and blood-donation testing to prevent the transmission of disease through blood transfusion.

In most jurisdictions, courts have applied the professional negligence standard and required only that the actions of blood-collection facilities be measured against the conduct of other members of the defendant's profession, through the testimony of expert witnesses. In those jurisdictions, blood collectors whose donor-screening and donation-testing procedures conformed to the standard of care in the profession and, in particular, the recommendations of standard-setting organizations such as AABB, the Food and Drug Administration (FDA), and the Centers for Disease Control and Prevention (CDC) have not been held responsible for transmission of a disease. In these cases, courts reject allegations of alleged failure to screen donors[13,21] and failure to implement tests not yet adopted by standard-setting organizations or mandated by government agencies.[22,23]

This articulation of the professional negligence standard was most recently applied in a case involving transfusion-related acute lung injury (TRALI). Although not an infectious disease risk, TRALI is, as of today, the most commonly reported cause of transfusion-related death in the United States, surpassing deaths caused by ABO incompatibility and bacterial contamination.[24] Unfortunately, because this clinical syndrome remains poorly defined and its pathophysiology is not understood, the medical community lacks consensus as to the appropriate way to prevent the syndrome. An interesting and illustrative case is presented in Box 17–5.

The court specifically noted that the plaintiff's malpractice contentions with respect to the blood center were that the blood products administered to the patient should have been screened for antibodies and that the entire blood-banking community was negligent for failing to follow this practice. The court dismissed the case, finding that the plaintiff had failed adequately to dispute the defendants' proof that the decedent's "treatment was consistent with good and acceptable medical practice."

BOX 17–5 ***Illustrative Case***

In *Boland v. Montefiore,*[14] a patient diagnosed with myelogenous leukemia underwent a bone marrow transplant and was told by his treating physician that he required outpatient transfusions to increase his platelet count. The hospital blood bank director responsible for the management of outpatient transfusions performed in the blood center was present in the blood bank during the transfusions. The first two units were transfused without incident; however, during transfusion of the third unit, the patient experienced shortness of breath. Although all appropriate actions were taken, including stopping the transfusion and providing emergency care, the patient suffered cardiac arrest and died. The patient's estate filed suit against the blood center for negligent screening and testing of the units and failure to prepare properly the blood administered to the plaintiff. The treating and transfusing physicians, as well as the hospital, were sued for conscious pain and suffering, wrongful death, and failure to obtain informed consent.

In other jurisdictions, however, the question of a defendant's negligence concerning donor screening or testing has been judged under a different application of the professional negligence standard. Specifically, the highest state court in Colorado overturned a verdict rendered in favor of the blood center and held that a blood collector's compliance with governmental regulations and the standards and guidelines of a professional association was not conclusive proof that additional precautions were not required, because some other blood centers were using "additional precautionary measures."[25] When evidence concerning the appropriate standard of care is broadened to include not only the testimony of expert witnesses but also the practices of other individual blood centers, courts have determined that sufficient conflicting evidence exists about the standard to create a question of fact to be determined by a jury.

Even if a traditional professional negligence standard is applied, once the testimony of experts creates a question of material fact for the jury, the specific instruction to the jury on the standard becomes exquisitely important in determining the outcome of the case.

In *Ray v. American National Red Cross* (ANRC),[26] the plaintiff argued that the ANRC was obliged to act as a reasonable blood bank with the knowledge and skill level similar to that of the ANRC, whereas the ANRC contended that it had only to act according to industry standards. In applying the ordinary negligence standard, the appellate court reasoned that, "particularly where the Red Cross is in a position to substantially establish the industry standard, it may not use that standard as a safe harbor to insulate its activities from scrutiny if competent evidence demonstrates that it would have been reasonable for the Red Cross to adhere to a higher standard or a different practice."[26]

As a practical matter, the outcome of any case that challenges donor-screening or -testing practices will largely depend on the specific facts presented, including the specific time and circumstances of the harm or injury. The *Boland* case (see Box 17–5), which involved a patient who died of TRALI and allegations of a failure to screen donors in 1995, was successfully defended.[14] Whether that same case could be successfully defended today is uncertain, as several options

for mitigating the risk of TRALI have recently been presented and discussed at a consensus conference.[27] Although the panel stopped short of recommending that any specific intervention practice be adopted, some major blood-transfusion systems, including the National Blood Service in the United Kingdom, have implemented practices to mitigate the risk of TRALI.[28] As practices in the profession change, so too does the standard of care against which facilities and individuals are judged.

A few of the changing standards of practice are discussed later.

CHANGING STANDARDS OF CARE IN TRANSFUSION MEDICINE–RELATED CASES

Bacterial Contamination

Prior to 1995, virtually no filed cases involved negligence in testing or screening to prevent transfusion-associated morbidity and mortality from bacterial contamination of platelet or red blood cell units. One of the few reported cases of bacterial contamination calls into question not the failure to test, but the failure to provide directed donations as an alternative to conventional transfusions. In 1995, a woman who received a transfusion of two units of packed red blood cells in the course of coronary bypass surgery developed sepsis and died the day after her surgery.[29] It was later determined that her death was caused by an extremely rare blood-borne bacterial infection. The woman's family claimed that the medical facility was negligent in refusing their request for directed donation of blood and that this refusal was the proximate cause of death. The judge awarded the woman's family $400,000; however, the medical facility appealed, and the finding was reversed. The appellate court specifically determined that the applicable standard of care should reflect the community standard of care, including FDA and/or AABB recommendations and standards, not just the hospital's internal policies.

Then, in 1997, the family of a man who died of transfusion-associated sepsis brought suit against a hospital in Providence, Rhode Island, and was awarded $5.6 million.[30] Although the plaintiff alleged that the hospital was negligent in failing to prevent transfusion of the contaminated unit, the jury appeared to base its award on the alleged failure of the hospital to recognize and treat the infection. With the implementation of AABB Standard 5.1.5.1,[31] requiring that blood collectors and transfusion services have in place a method both to limit and to detect bacterial contamination in platelet components, undoubtedly increased attention will be focused on adverse reactions in patients related to undetected bacterial contamination.

Given evolving technologies, ongoing determination of residual risk, and the lack of uniform methods for meeting AABB Standard 5.1.5.1, the possibility of exposure to a lawsuit for injuries relating to death or injury resulting from bacterial contamination is real. Bacterial contamination of platelets has been one of the greatest transfusion-transmitted infectious risks in the United States, and is now significantly higher than the risk of transfusion-transmitted viral infection.[32] Although lack of consensus appears to be present as to the best way to eradicate the risk, transfusion-medicine professionals clearly now have a duty to try to minimize the risk through available means.

What is not as clear is the effect of divergent practices on a defendant's ability to avoid a risk of litigation. The increasing trend toward the use of single-donor platelets, the debate over the necessity of testing for aerobic as well as anaerobic bacteria, and the discrepancies in the relative predictive value of available test methods[33] may constitute grounds for negligence claims. The true measure of potential legal exposure, however, will be the incidence and severity of the adverse reactions relating to the transfusion of bacterially contaminated units. Current anecdotal survey data and data from some larger facilities suggest that morbidity and mortality directly relating to failures to implement two-bottle culture systems, eliminate or reduce the use of pooled platelets, or substitute more sensitive and specific testing will be limited.

West Nile Virus and Variant Creutzfeldt-Jakob Disease

The transmission of West Nile virus (WNV) or variant Creutzfeldt-Jakob Disease (vCJD) through blood transfusion is often proffered as a source of potential liability for blood collectors, hospitals, and transfusing physicians. These two threats and the blood community response to each are illustrative of two separate approaches to mitigating transfusion risk. As a practical matter, however, the blood community's rapid and system-wide response to both of these threats mitigates the risk of liability for blood-transfusion professionals.

The management of the WNV threat to blood safety serves as a model for effective threat containment. Beginning with the first diagnosis of potential TT-WNV in 2002,[34] through the implementation of donor screening[35] and inventory management to reduce the risk of distribution of infected units[36,37] to the implementation of pooled[38] and then individual nucleic acid testing (NAT) in high-incidence locations,[39] the response of the government and the private sector was swift, coordinated, and evidence based.[40] Although a number of blood recipients were infected with WNV through transfusion, the broad-based development of national recommendations for donor screening and inventory management, as well as the rapid development and implementation of testing for the virus, established a clear national standard of practice against which blood-center and transfusion-service response could be measured.

The management of vCJD as a risk of blood transfusion has proven to be more difficult. The primary method for controlling the risk of vCJD has been the implementation of geographic and time-defined donor exclusions.[41] As a method for mitigating risk, these deferrals, which are based in part on scientific data and in part on the need to maintain public confidence in the safety of the blood supply, are neither sensitive nor specific. Yet, with the publication of FDA guidance on the issue[42] and the adoption of donor-exclusion criteria in other countries, it is unlikely that a plaintiff who contracted vCJD through blood collected and issued by a facility that followed these recommendations could successfully argue negligence.

The primary reason that a case alleging the negligent transmission of vCJD through blood transfusion is likely to fail is the difficulty of proving causation, and, specifically, associating transmission of the disease with a particular unit, as no specific test exists for the pathologic prion at the time

of this writing. In addition, given the extremely low prevalence of vCJD in the human population, it is evident that only a small number of cases, if any, will occur.

Component Processing

In the blood-transfusion field, significant discussion has occurred over the potential for increased liability relating to the failure to adopt certain component-processing steps. As an example, increasing consensus is found that certain patients will benefit from receiving leukocyte-reduced red blood cells. The failure to prescribe leukocyte-reduced red cells for patients who have previously experienced febrile nonhemolytic transfusion reactions, those who need cytomegalovirus (CMV)-safe units, or those who need to have their risk of human leukocyte antigen (HLA) alloimmunization limited can create a potential risk of liability for a transfusing physician. Conversely, the obligation to provide leukoreduced units to every patient (universal leukoreduction) has not been clearly established. Conflicting, underpowered, and inconclusive studies,[43–46] as well as the very public and documented discussion over the cost/benefit ratio of leukoreduction,[47] suggest that similar debates over leukoreduction would be repeated in any litigation asserting the obligation to provide leukoreduced units to all patients. In addition, because many of the asserted benefits of leukoreduction are difficult to capture in a single episode (e.g., the prevention of immunomodulation or the transmission of viruses not invariably associated with symptomatic disease) and because many of the risks of not using leukocyte-reduced units can be masked or corrected through the administration of other drugs (e.g., acetaminophen for fever reduction), both causation and the specific injury to the plaintiff would likely to be difficult to establish.

The utility of irradiation of blood components is another area in which consensus has not yet developed. Most physicians recognize the utility of blood-component irradiation to prevent graft-versus-host disease (GVHD) in certain at-risk patients.[48] The literature strongly supports the conclusion that patients with hematologic malignancies, patients with congenital immunodeficiencies, patients who are receiving allogeneic bone marrow transplants, and patients who receive intrauterine or exchange transfusion should receive irradiated blood components (see Chapter 28). However, some documented medical cases exist in which the implementation of universal irradiation would have prevented the death of patients not known to be at risk.[49,50] Although some in the transfusion-medicine community have advocated the adoption of universal irradiation of blood components, others debate whether the high severity and low frequency of these adverse events warrant the implementation of universal irradiation. Nonetheless, facilities must keep abreast of the growing body of literature on patients who may benefit from receiving irradiated units.

Donor Injury

With an overall frequency of donor complications reported as approximating 20% on average and including severities of reactions from bruising to death, blood-collection facilities have policies and procedures in place to minimize the risk of both donor injury and litigation resulting from injury. Best practices require a facility to continually update the information in the consent for donation, to have a plan for adverse reactions at the donation site, and to provide donors with postdonation care and contact information. Most facilities also have adopted a policy of paying for immediate emergency care in the event an injury occurs.

Such preventive measures are critically important because, as previously noted, areas of activity in blood collection and transfusion services may be analyzed under principles of ordinary negligence, as opposed to the professional negligence standard. Instructive examples are described in Box 17–6.

Although it is difficult to predict which standard will be applied in all situations, a blood-collection facility will be best protected by an annual review of its policies and procedures against what a reasonable donor might understand and expect.

BOX 17–6 *Illustrative Cases*

McDonnell v. American National Red Cross[51] revolved around a donor who fainted immediately after blood donation while walking unescorted from the donation table across a stone floor to the snack table and suffered a concussion and a postconcussion syndrome. The court, in an unpublished opinion, adopted ordinary negligence as the applicable standard of care rather than medical malpractice, because the complaint took issue with the general safety and operation procedures surrounding the blood donation—facts within the common knowledge and experience of the jury—and did not raise questions requiring medical judgment.

On the contrary, *Baumann v. American National Red Cross*[52] involved a donor whose right median nerve was injured during phlebotomy. The plaintiff sued the American National Red Cross under an ordinary negligence theory, alleging failure to warn of the potential for injury to donors during phlebotomy and negligence in the phlebotomy procedure. The court held that the claim should have been brought under the state's medical malpractice statute, reasoning that the standard of care governing these types of claims clearly involves medical learning or principles and is not within the knowledge of most laypeople.

Informed Consent

The doctrine of informed consent has its origins in the legal theory of battery or nonconsensual touching.[53] Although this legal theory is sometimes referenced in case law involving the failure to obtain informed consent, more recent cases base the legal theory on negligence.[54] Whichever theory serves as the basis for the analysis, it is clear that the ethical principle of autonomy, or the individual's right to make choices about personal matters, is well ingrained in the legal system. Multiple cases in virtually every jurisdiction reinforce the legal obligation to obtain informed consent for most medical treatments or interventions, including blood transfusion.

With the exception of federal regulations applicable to patients participating in research protocols, the law of informed consent is governed by state law, which varies from jurisdiction to jurisdiction. Some states, notably California, New Jersey, and Pennsylvania, have enacted statutes that delineate specific steps that must be taken in the informed-consent process. In other states, informed-consent requirements have been developed through case law.

Failure to obtain informed consent also has become an issue in clinical trials. In a relatively recent case, *Wright v. Fred Hutchinson Cancer Research Center*,[55] patients and their

families brought a class action against the hospital and four physicians after 80 of 82 patients receiving care under a certain protocol, designed to reduce the risk of GVHD, died. The plaintiffs claimed that the center failed to inform them adequately about the risks inherent in the T-cell–depletion protocol. Although the case never went to trial, apparently because of the inability to certify the class, one of the evidentiary rulings precluded summary judgment in favor of the cancer center, creating the inference that the center could have been found liable for failure to inform.

As informed consent for blood transfusion has become the standard of practice, the elements of effective informed consent have become more standardized. The process includes (1) disclosure of the risks and benefits of transfusion or related therapies, (2) presentation of the potential alternatives, (3) an opportunity to ask questions of learned professionals,[56] and (4) documentation of the consent. Although these elements are straightforward, identifying which risks must be disclosed has been the subject of significant case law and has resulted in the development of two different standards. The first and older standard requires the disclosure of risks that are considered to be material to the reasonable physician.[57] This standard, however, has been replaced in a majority of jurisdictions by a newer standard, which requires the disclosure of risks that would be considered to be material to a reasonable patient.[58]

The adoption of the "reasonable patient standard" has introduced additional issues for transfusion-medicine professionals. Specifically, (1) the relevant risks must be disclosed, (2) the disclosure must be in language understandable to the patient, and (3) a new informed-consent discussion is required if a substantial change in circumstances, whether medical or legal occurs.[56]

Who Has the Duty to Obtain Informed Consent?

Courts have not been consistent in deciding who specifically has the obligation to provide the information and to obtain informed consent. Generally, the obligation to obtain informed consent has been considered to be that of the treating physician, who is the professional most likely to have developed a relationship with the patient. In the transfusion setting, however, this question is more complex, and some courts have reasoned that a physician who refers a patient for surgery is not responsible for obtaining informed consent for transfusion; rather, it is the surgeon who performs the procedure who has the duty to obtain informed consent.[59] This line of cases does not automatically implicate all surgeons assisting in the surgery. Some cases have held the primary surgeon responsible, while refusing to hold assisting physicians responsible for the failure to obtain informed consent.[60] In some circumstances, however, physicians may delegate the duty to obtain informed consent to other health care providers.[61]

For the most part, hospitals have not been held to owe a duty to patients to obtain informed consent,[62] because the obligation to do so is generally that of the physician who ordered the transfusion. However, as the requirement to obtain informed consent becomes incorporated into the requirements of standard-setting organizations like the Joint Commission on the Accreditation of Healthcare Organizations (JCAHO)[63] hospitals increasingly will be held accountable for ensuring that informed consent is obtained.

Courts in several jurisdictions have relied on additional theories of liability, including the "corporate negligence theory,"[64] under which a hospital may be liable for failing properly to oversee the treatment of patients or require physicians with hospital privileges to obtain informed consent. Another theory is "respondeat superior," under which an employer is responsible for its employees and, particularly, has a duty to exercise reasonable care in selecting, retaining, and supervising medical staff.[65] In addition, an institution that voluntarily assumes this duty, but fails effectively to obtain the consent, can be held liable for injury relating to those failures, even in the absence of an original duty to obtain consent.

Separate from any specific duty to obtain informed consent, hospitals do have a duty to educate their physicians about risks, including the risks of transfusion. Hospitals are independently responsible for providing information sufficient to allow a treating physician to carry out his or her duty to obtain informed consent. In the transfusion setting, this means that hospitals must have information available to physicians on transfusion risks, as well as available alternatives to allogeneic transfusions.[66]

Alternatives

One of the elements of informed consent is the obligation to advise the patient of alternatives to the recommended therapy. This particular element raises some interesting questions about the obligation to provide information about alternatives to conventional transfusion therapy. Courts have had numerous opportunities to consider the liability of physicians for failing to recommend alternative procedures, such as autologous and directed donations, as well as other alternatives to allogeneic transfusion. This complex issue is based primarily on two questions: the standard of practice in the community (including the availability of the alternate therapy), and the hospital or blood bank's adherence to its own policies and procedures.

In one case, a California court held that a blood center could not be held liable for failing to disclose the option of a directed-donation program because the plaintiff had failed to show that these programs were standard practice in the community.[66] Interestingly, the blood center in this case did have a directed-donation program, but not for patients with the plaintiff's specific illness, which required multiple transfusions.

The outcome of these cases is often directly affected by the expert testimony presented. In *Spann v. Irwin Memorial Blood Centers*,[66] the plaintiffs failed to offer testimony regarding the standard of practice in the community. If expert testimony supporting the general availability of directed donations or other alternative therapies had been presented, it is possible that the testimony could have been sufficient to defeat a motion for summary judgment. This would have created a question of fact for the jury, provided that the failure to follow the standard practice was causally connected to the injury. It is, however, noteworthy that hospitals and blood-collection facilities have successfully defended against allegations that the failure to provide directed donations constitutes negligence by introducing evidence that directed donations are not necessarily safer, and possibly even less safe, than regular donations.[67]

In other cases, the interplay between the testimony of experts and the availability of the optional therapy determines the outcome of the case. In *Doe v. Johnston*,[68] the

plaintiff offered testimony on the superiority of autologous transfusion, but conflicting evidence over the "reasonable availability" of the procedure in 1985 created a question of fact sufficient to uphold the trial court's denial of a request for a directed verdict in favor of the plaintiff.

As the type and availability of alternative therapies to blood transfusion continue to grow, the obligation to inform potential recipients about the availability of these therapies will increase. In addition to preoperative autologous donation, many hospitals now offer intraoperative blood salvage, postoperative blood salvage, and acute normovolemic hemodilution. Not every alternative is either appropriate for, or available to, every patient. To the extent that an option is available and appropriate for a particular procedure, and the patient is not informed of the option, any complication from an allogeneic unit can create potential liability for a physician or hospital.

Less clear is whether a hospital would be held liable for failing to make these alternative therapies available for patients. Case law from the HIV litigation, discussed earlier, suggests that a hospital would not be required to offer alternative therapies that are so new that they have not yet become accepted as the norm. To the extent that a hospital offering bloodless surgery is located in or near other hospitals, its physicians could rely on the fact that the patient has the option to choose to have a procedure performed at a different location. It is possible, however, that an expert witness testifying that the availability of these alternatives is now the standard of care could create a question of fact for the jury.

In still other cases involving an alleged failure to inform a plaintiff of alternative procedures, the determining issue is not the availability of the alternative, but a hospital or blood center's adherence to its existing internal policies. In *Doe v. American National Red Cross*,[69] a hospital that failed to inform a plaintiff about the option of directed donations was denied summary judgment, at least in part, because a policy allowing such donations existed within the hospital. Again, the outcome of many of these cases is fact-specific and depended not only on the availability of an alternative therapy, but also on the question whether the available therapy would be appropriate for the specific patient.

Medically Necessary Transfusions

Beginning in the 1980s, many plaintiffs brought cases against physicians and hospitals based on the theory that the transfusion that caused injury to the patient was not medically necessary. The lack of reference standards or universally accepted comprehensive transfusion guidelines, as well as regional variations in transfusion practice, contributed to the unpredictable outcome of these cases. In addition, expert testimony is critical to defining the appropriate standard of care in these cases. One of the most interesting and troubling cases for transfusing physicians is presented in Box 17–7.

Once a case challenging the medical necessity of a particular transfusion becomes a battle of the experts, the outcome is difficult to predict, but juries have found hospitals and physicians liable for injuries on the basis of expert testimony about the necessity of the transfusion.[71] Case dicta, as well as experience, underscore the importance of hospital policies and hospital transfusion guidelines, as well as the review of transfusion practice in the hospital transfusion committee.

Some courts, applying a broad definition of foreseeability, have allowed cases to proceed against physicians whose prior negligence required the transfusion that transmitted HIV.[72] In other cases, applying a narrower interpretation of foreseeability, courts have granted summary-judgment motions in favor of defendant physicians who provided negligent treatment that required transfusion because the outcome of the transfusion was not foreseeable.

BOX 17–7 *Illustrative Case*

Oiler v. Willke[70] demonstrates what can happen when expert testimony and a broad interpretation of a reasonably foreseeable injury coincide in the same case. *Oiler* involved a platelet transfusion that allegedly resulted in the transmission of human immunodeficiency virus (HIV). The plaintiff presented expert testimony that the platelet transfusion was unnecessary. Although the transfusion was administered in 1980, at a time when the transmissibility of HIV through blood transfusion was not yet established, the court ruled that the plaintiff had established a genuine issue of fact as to whether the transmission of HIV was foreseeable because the plaintiff had presented evidence that many viruses, including hepatitis, were known to be transmissible through blood transfusion.

Blood Administration

Now that the risk of transfusion-transmitted diseases has dramatically decreased because of donor screening and increasingly sensitive testing, more attention is being placed on injuries resulting from improper administration of blood and blood components. Currently, one of the leading causes of death relating to transfusion is mistransfusion, or administering the wrong unit to the wrong patient. Although not many cases have been reported, plaintiffs are most likely to be successful if they allege medical negligence in the transfusion of the unit. In *Walker v. Humana Medical Corporation,*[73] a phlebotomist failed to draw blood from the proper patient. The resulting transfusion caused a reaction due to the incompatible blood, and the court found sufficient evidence of wantonness, or knowledgeable malfeasance, to present the facts to a jury.

Theories of breach of contract or of implied warranty generally will not apply in these cases because usually it cannot be demonstrated that the unit of blood itself is defective. Although logic suggests that every case of mistransfusion results in a legal action, few legal cases or rulings involve these types of injuries, presumably because most of these cases are settled by hospitals out of court. Given the existence of devices that can prevent mistransfusion, constructing a successful legal defense to these cases is difficult.

PRIVACY AND SECURITY CONCERNS UNDER HIPAA

Invasion of Privacy

Invasion of privacy is the unwarranted appropriation or exploitation of one's personality, publicizing one's private affairs with which the public has no legitimate concern, or wrongful intrusion into one's private activities, in such a manner as to cause mental suffering, shame, or humiliation to a person of ordinary sensibilities.

Right to Privacy

Although not explicitly stated in the Constitution, "a right to be left alone" began to emerge in the late 1800s. This right has evolved into a liberty of personal autonomy protected by the 14th amendment of the United States Constitution. Along with the constitutional right of privacy, states have adopted statutory rights of privacy that limit access to personal information, and the Federal Trade Commission (FTC) protects the public's financial privacy through legislation such as the Right to Financial Privacy Act of 1978[74] and the more recent Financial Services Modernization Act of 1999.[75]

Most recently, federal and state privacy laws protect health-related information.

HIPAA

With the passage of the Health Insurance Portability and Accountability Act of 1996 (HIPAA),[76] as amended, which became effective for most "covered entities" on April 14, 2003, practices relating to the use and disclosure of medical information have been subject to increasing attention. The federal privacy regulations that implement portions of HIPAA ("Privacy Rules") were designed to combat fraud and abuse in health care, standardize the electronic exchange of administrative and financial data, and protect the privacy and security of individual health information.

Covered Entities

"Covered Entities" generally include health plans, health care clearinghouses, and health care providers.[77] A health care provider is a covered entity under HIPAA if it (1) meets the definition of "health care provider;" and (2) transmits health information in electronic form in connection with covered transactions. Independent blood suppliers who do not perform patient-related health care activities are specifically exempt from the provision of the act, as they engage in "activities related to the procurement or banking of blood, sperm, organs, or any other tissue for administration to patients."[78]

However, an entity's status as a "covered entity" requires a careful, fact-specific analysis of all of the activities provided by the facility in question. The Department of Health and Human Services (HHS) has stated, "the procurement or banking of organs, blood (including autologous blood) … or any other tissue or human product is not considered to be health care under this rule and the organizations that perform such activities would not be considered health care providers when conducting these functions."[79]

Under this definition, if a facility is involved in activities other than the procurement and banking of blood, such as laboratory testing used to diagnose or otherwise treat a patient, as opposed to simply performing blood screening, it may be providing patient-related services that bring it under the definition of "health care provider" under HIPAA. It is not clear whether a facility that performs cross-matching and other compatibility testing would be considered a health care provider. To be considered a covered entity, the health care provider must also meet the second criterion: it must be transmitting protected health information in electronic form in connection with one of the "standard transactions" listed in the rules.

Covered entities must comply with numerous and extensive requirements under the Privacy Rules, including administrative, physical, and technical safeguards under the HIPAA Security Rule,[80] which are designed to safeguard electronically protected health information. Generally, covered entities may use protected health information only as it relates to treatment, payment, or health care operations.[81] Covered entities must make reasonable efforts to limit the use or disclosure of, and requests for, patient health information (PHI) to the minimal amount necessary to accomplish the intended purpose. Covered entities are required to develop written policies and procedures that are summarized in a "Notice of Privacy Practices" that is publicly available.[82] Noncompliance with the Privacy Rules may result in civil and criminal penalties.[83]

Business Associates

Even facilities that are not covered entities under HIPAA may have to comply with certain requirements if they are "business associates." Covered Entities are required to enter into business associate agreements with persons and organizations that perform functions or activities on their behalf and receive PHI in connection with these services for other than treatment purposes. Common examples of business associates are accountants, consultants, administrators, and financial services. HIPAA specifically includes accreditation as an activity, giving rise to a business associate relationship.

Business associate agreements principally are designed to ensure that business associates and those acting on their behalf use the PHI only for the purposes that they are engaged to perform or as otherwise required by law; safeguard the information from disclosure and misuse; promptly report any disclosure to the Covered Entity; and assist the Covered Entity in complying with HIPAA requirements.

Criminal Penalties

In June 2005, the U.S. Department of Justice (DOJ) clarified who can be held criminally liable under HIPAA. Covered entities and those individuals that "knowingly" obtain or disclose individually identifiable health information in violation of the applicable regulations may face criminal liability. The DOJ interpreted the "knowingly" element of the HIPAA statute for criminal liability as requiring only knowledge of the actions that constitute an offense. Specific knowledge of an action being in violation of the HIPAA statute is not required.[84]

In 2004, the U.S. Attorney in Seattle announced that a hospital phlebotomist was being indicted for violating the HIPAA privacy law.[85] The phlebotomist had allegedly accessed the medical records of a patient with a terminal cancer condition, obtained credit cards in the patient's name, and run up more than $9,000 in charges. In a statement to the court, the patient said he "lost a year of life both mentally and physically dealing with the stress" that resulted from the phlebotomist's actions. The guilty individual signed a plea agreement and was sentenced to 16 months in jail. At the time, the DOJ trumpeted the first HIPAA criminal prosecution. The DOJ site announced: "This case should serve as a reminder that misuse of patient information may result in criminal prosecution."[85] Under its new legal opinion, however, the phlebotomist could not be prosecuted further under HIPAA because, arguably, he did not knowingly violate HIPAA. Whereas HIPAA protects the health information of individuals, it does not create a private cause of action for those aggrieved. State law, however, may provide other

avenues of liability. Generally, HIPAA does not preempt state privacy laws or professional licensure requirements, so that determining compliance requires examining the relevant state's confidentiality laws.[86]

EXTRAPOLATION OF THE TRANSFUSION LEGAL EXPERIENCE

The legal precedents established in transfusion cases have application to other areas. Notably, the collection, processing, manipulation, and administration of cellular therapy products raise legal issues similar to those presented in transfusion cases. Although the actual requirements for cellular therapy donor screening and unit testing may ultimately differ from those applicable to blood donors and blood components, the case law concerning the appropriate negligence standard and the legal requirements for defining the standard of care against which actions are to be measured will influence the outcome of cellular therapy litigation.

An additional legal risk in the collection, processing and administration of cellular therapy products, not generally present in transfusion medicine, is the relative efficacy of processing protocols for cellular therapy products. Unlike blood components, which are basically licensed generic biologics, most cellular therapy products are developed under highly individualized collection, processing, manipulation, freezing, and/or thawing protocols. Although some of these protocols and methods are protected intellectual property, others are in the public domain and thus are available for use. One of the areas of legal concern will be the extent to which these different processes are associated with varying engraftment survival rates. As in the transfusion field, the testimony of experts will be key to the outcome of litigation in this area.

In the cellular therapies arena, the proliferation of clinical trials will also draw increased attention to the informed-consent process. The failure to have in place or to follow a well-thought-out process will most certainly lead to legal problems. In addition, given the vulnerability of expectant parents, issues related to informed consent for cord blood donation, particularly in cord blood banks that collect and store these units for use by the family, will pose legal concerns for institutions that provide this service.

Finally, facilities that store cord units for future use by the family may find that issues surrounding the obligation to store and, in some cases, dispose of these collected units may raise contract, as well as negligence, issues. Although the intricacies of contract law are beyond the scope of this chapter, facilities that store cord blood units should have all storage contracts carefully reviewed by legal counsel. Even the best contracts cannot completely protect a facility against legal liability in the event that a facility negligently loses or renders unusable a cord blood unit. In this event, as in the case of blood donor injuries, the actions or inactions of the facility are likely to be judged against an ordinary negligence standard.

DEFENDING AGAINST LEGAL RISKS

In addition to preventive measures for avoiding litigation, litigation strategies can help expedite resolution of issues and, if all else fails, affirmative defenses can be used effectively to defend against litigation.

Preventive Measures

One theory to be considered is that patients who have suffered from medical errors are motivated not so much by the prospect of economic compensation, as by the desire to ensure that the error is not repeated. A pilot mediation conducted under the sponsorship of the Massachusetts Board of Registration in Medicine confirms this theory and strongly suggests that private dispute resolution through mediation improves the outcome for all concerned. As Ed Dauer, one of mediation's key proponents suggests, "For its part, mediation, when properly employed, can be private, integrative, safe, nonjudgmental, and flexible in scope, process, and outcome. It can be a safe harbor with therapeutic potential, and can offer its participants the opportunity to address the source as well as the consequence of the immediate problem. Mediation may, in short, offer a process whose traditional attributes are consistent with, rather than antithetical to, the requisites of quality improvement."[87]

Some lawyers have embraced variations of these concepts in the form of "good-faith conferences" and "apology meetings." The good-faith conference is geared toward furnishing the plaintiff with the opportunity to vent his or her anger at the defendant. The conference may be a condition to settlement, or it may follow settlement. No apology is promised or expected, but apologies often develop during well-managed meetings. The apology meeting is similar, except that an apology from the defendant is expected, along with a therapeutic discussion.

Both types of meetings must be carefully planned and skillfully executed. It is imperative that all parties have a certain level of trust in one another and that all are committed to conducting the meeting in a civil and nonthreatening manner.

Litigation Strategies

It is not uncommon for plaintiffs in transfusion-related litigation to file suit against as many defendants as ethically possible to maximize the chances of finding a culpable "deep pocket." Typically, the treating physician and other medical professionals involved in the administration of transfusions, along with the hospital, the blood bank, and even AABB, will be named as defendants. Although the first reaction among co-defendants is to point fingers and assign blame, a more productive approach often is to work together on a common defense. Not only can this cooperative approach result in stronger defenses, but it can significantly reduce legal bills, as well.

Affirmative Defenses

Even if a plaintiff is able to prove all four elements of negligence, a defendant can raise defenses that minimize or defeat the plaintiff's claims. One such defense is that the plaintiff failed to bring the lawsuit within the legal time limits set by the jurisdiction where the case is being brought. This defense is referred to as the statute-of-limitations defense.

Another affirmative defense available in many jurisdictions is that the actions of the plaintiff contributed to the cause of the injury. This theory is called contributory negligence or comparative negligence on the part of the plaintiff. Contributory or comparative negligence is a legally contributing cause, in addition to the negligence of the defendant, in bringing about the plaintiff's harm.

A related affirmative defense is that an unforeseeable intervening event caused the injury, rather than the defendant's negligence.

LESSONS LEARNED

By applying the difficult lessons learned from the HIV-related transfusion litigation to cases appearing on the horizon, it is possible to avoid litigation, or at least minimize its impact. One key lesson is the importance to medical facilities of promptly implementing government recommendations and standards adopted by private organizations. Another lesson is to consider all available scientific evidence continually and to keep abreast of best practices, especially those relating to new techniques, technologies, and medical challenges, to anticipate the adoption of a practice as the standard of care.

Equally important, particularly in situations in which lack of consensus exists regarding how to manage a particular risk, is the demonstration that a facility is knowledgeable about the risks and has considered the available options.

Finally, efforts such as consensus conferences and workshops that attempt to establish a consensus or practice within the professional community are extremely important. Even such simple efforts as the development and adoption of a uniform donor-history questionnaire can ensure the recognition of clear standards of care.

Minimizing the risk of legal liability in the transfusion setting is not difficult, but in today's litigious society, eliminating that risk entirely is not possible. The most important preventive measures have been and remain using best practices, engaging in effective risk communication with patients, and taking swift corrective action when problems inevitably occur. Keeping current with standards of practice and effectively educating staff about those standards is essential to fending off legal claims. By taking these proactive steps, it will be possible to demonstrate, to the extent possible, that the physician or facility conformed to the currently accepted standard of care in the transfusion and cellular therapy communities. This will allow the professional to spend much less time defending past activities and devote considerably more valuable time to serving donors and patients.

D. Specific Blood Components

Chapter 18

Packed Red Blood Cells and Related Products

Sally A. Campbell-Lee • Paul M. Ness

Landsteiner[1] discovered the ABO system in 1901, more than 100 years ago. Since that time, the development of a safe and effective anticoagulant-preservative solution[2] and the efforts in World War II that led to current methods of organized blood collection[3] have promoted transfusion medicine to an essential aspect of clinical medicine. The appropriate use of red blood cell concentrates (commonly referred to as packed red blood cells, pRBCs) depends on knowledge of the physiology of RBC transfusion and the therapeutic options of various component manipulations (Table 18–1). This chapter covers the manufacturing, storage, and indications for whole blood, pRBCs, and related products.

COLLECTION

In 2001, nearly 15 million units of whole blood were collected in the United States.[4] Whole blood, composed of RBCs, leukocytes, platelets, and plasma, is collected into a closed, sterile system. The system consists of a phlebotomy needle, integral donor tubing, and several attached polyvinyl resin bags.[5] Within the polyvinyl resin bags is 63 mL of, most commonly, citrate, phosphate, and dextrose (CPD) or citrate, phosphate, dextrose, and adenine (CPDA-1) anticoagulant-preservative, which provides a shelf-life of 35 days when the contents are stored at 4°C. Including the anticoagulant-preservative, the volume of a unit of whole blood is approximately 510 mL (450 mL of blood plus 63 mL of anticoagulant),[6] although many blood centers now collect 500 mL of donor blood. Within 24 hours of collection, the platelets (if refrigerated) and granulocytes are dysfunctional, and several coagulation factors are at suboptimal levels.[7] To optimize factor activity and platelet recovery, preparation of fresh frozen plasma (FFP) and platelet concentrates must occur within 8 hours.[8]

One of the problems with the standard method of collecting whole blood is that the amount of anticoagulant-preservative is predetermined, but the exact amount of whole blood collected is not. Because of variability in donor hematocrits, different RBC masses are collected per unit, resulting in variable RBC mass provided per unit transfused.

Table 18–1 **pRBC Characteristics and General Indications**

Product	Manipulation/Comment	Indications
Whole blood	None	Trauma, massive surgical bleeding
pRBCs, unmodified	Volume reduced	Symptomatic anemia Hemorrhagic shock (with volume expanders)
pRBCs, leukoreduced	White blood cell reduction	Prevent transfusion reactions Reduce alloimmunization Reduce infectious diseases Minimize immunomodulation
pRBCs, washed	Plasma removal	Recurrent severe allergic reactions IgA deficiency with anti-IgA
pRBCs, irradiated	Inactivation of lymphocytes	Prevention of TAGVHD
pRBCs, frozen deglycerolized	Frozen with subsequent deglycerolization Facilitates long-term storage	Storage of rare RBC phenotypes Autologous storage
pRBCs, CMV seronegative	Tested and found to be negative serologically Also applies to leukocytes, platelets, and residual plasma	CMV-negative transplantation Low-birth-weight infants CMV-negative pregnant women In utero transfusion

CMV, cytomegalovirus; IgA, immunoglobulin A; RBC, red blood cell; TAGVHD, transfusion-associated graft-versus-host disease.

A more efficient method of collecting RBCs for transfusion has been developed. RBCs may be collected by apheresis, with the unwanted components returned to the donor. Apheresis has become commonplace in the collection of platelet concentrates and granulocytes. Modified apheresis equipment has been used to collect RBCs and plasma.[9] The MCS+ machine (Haemonetics Corp., Braintree, MA) was developed for RBC collection and is now approved by the U.S. Food and Drug Administration (FDA) for 2-unit apheresis with automated return of 500 mL of saline to the donor or collection of 1 unit of RBCs and 200 to 550 mL of plasma.[10] Other manufacturers have also developed automated RBC collection systems.

For whole blood collections, a donor must have a hematocrit of at least 38% or a hemoglobin level of 12.5 g/dL and must wait 56 days between donations.[11] The FDA criteria for allogeneic 2-unit apheresis red blood cell donation require a minimum hematocrit of 40% or a hemoglobin of 13.3 g/dL, with a minimum of 112 days between donations. Height and weight requirements ensure adequate donor RBC mass. For men, a minimum height of 5 feet 1 inch and weight of 130 pounds, and for women, 5 feet 5 inches and 150 pounds are required. The total volumes removed from the donor in 2-unit RBC apheresis (380 to 500 mL RBCs) are comparable to the total volumes removed during whole blood donation (405 to 495 mL). The percentage of total blood volume (8.7% to 10.5%) removed is less than the 15% total blood volume allowed in whole blood donation. RBC apheresis donors do not appear to have more symptomatic anemia than whole blood donors, and the most common reactions are attributable to citrate toxicity.[11] Additional details on this procedure can be found in Chapter 12.

The quality of apheresis-collected RBCs is comparable to that of manually collected RBCs. In a study by Holme and colleagues,[10] both 1-unit and 2-unit RBC apheresis was performed by using the MCS+ with CPD or CP2D preservative. After resuspension in AS-3 additive and storage for 42 days at 48°C, the apheresis units had slightly less hemolysis, lower supernatant potassium levels, and better tolerance for osmotic shock than did manually collected units, with no difference in RBC adenosine triphosphate (ATP) or 24-hour percentage recovery after autologous transfusion. The addition of an in-line white blood cell reduction filter now permits collection of 2 units of prestorage leukoreduced RBC concentrates.[12] On evaluation of RBCs collected by using the MCS+ with in-line filtration, the study showed that residual white blood cell counts were less than 0.4×10^6, below the current standard of 5.0×10^6.

RED BLOOD CELL PRODUCTS

Whole Blood

Although whole blood is rarely used, certain clinical situations exist in which it might be preferable to pRBCs. Whole blood can correct combined deficits in oxygen-carrying capacity and blood volume. Whole blood is thus potentially indicated in trauma and massive surgical bleeding when the blood type of the patient has been determined. This approach minimizes the use of RBCs and plasma from different donors, thus decreasing the risk of transfusion-transmitted infectious disease. In addition, one study demonstrated that a unit of fresh whole blood has a hemostatic effect equivalent to that of 8 to 10 platelet units[13]; this effect appears to be diminished after storage of the blood at 4–8°C for a period as short as 5 hours,[14] which makes whole blood impractical as a source of platelets.

Although fresh whole blood can be useful for patients who require both oxygen-carrying capacity and volume, adequate inventories are difficult to maintain. Most cases requiring whole blood involve trauma, emergency cardiovascular surgery, or liver transplantation, which can be difficult to predict. In addition, the community need for platelets and plasma must be considered. Therefore, although some have argued that whole blood should be used more often, even for certain elective surgeries, most trauma centers continue to manage their cases with pRBCs.[15]

Instead of whole blood, pRBCs and one of several volume expanders can increase oxygen-carrying capacity and volume. Volume can be replaced with crystalloid, which is not only sterile but also economical, in the setting of mild to moderate blood loss. With more massive transfusion, colloid oncotic pressure may have to be enhanced; colloid solutions such as albumin are preferred to plasma as no risk of transfusion-transmitted infectious disease exists. A study of patients massively transfused (defined as 10 or more units of RBC concentrates in 24 hours) and given crystalloid demonstrated that significant thrombocytopenia developed after 20 units of pRBCs. Significant prolongation of the prothrombin and partial thromboplastin times occurred after transfusion of 12 pRBCs.[16] Whether these laboratory values are actually associated with abnormal clinical bleeding deserves investigation.

Plasma is rarely indicated during massive transfusion unless a well-documented coagulopathy is found, as in liver failure or disseminated intravascular coagulation.[17] In some cases of trauma or cardiac surgery, platelet concentrates may be indicated as well to treat microvascular bleeding secondary to dilutional thrombocytopenia or platelet dysfunction secondary to bypass. When a pool of 6 random units or a single-donor apheresis unit of platelets is given, at least 300 mL of plasma is also infused, eliminating the need for concomitant administration of FFP.

pRBCs

pRBCs are manufactured by removal of the majority of plasma from a unit of whole blood. pRBCs have a volume of approximately 250 to 300 mL and a hematocrit of 65% to 80%. pRBCs prepared without further modifications contain white blood cells, platelets, and residual plasma. Transfusion of pRBCs is indicated in the treatment of anemia with symptomatic deficits of oxygen-carrying capacity and hemorrhagic shock when administered with volume expanders. One unit of pRBCs should raise the hemoglobin of an average adult by 1 g/dL and the hematocrit by 3%. For pediatric patients, the usual dose given is 3 mL/kg to raise the hemoglobin by 1 g/dL and the hematocrit by 3%.

PRESERVATION AND STORAGE

The ability of transfused RBCs to deliver oxygen to tissues and survive in the patient's circulation is the best measure of how well the RBCs were preserved and stored. Survival of transfused RBCs is acceptable when at least 75% of the transfused RBCs are present in the circulation for 24 hours.[6]

The development of blood preservatives provided a means to store RBCs to facilitate blood banking with minimally toxic anticoagulants. A long history of clinical development has provided preservative solutions that optimize storage length and in vivo function. The main areas that have been addressed are glucose, anticoagulation, ATP, and 2,3-diphosphoglycerate (2,3-DPG).

Glucose

Glucose is the main source of fuel for energy-requiring processes to preserve membrane function. Initially, dextrose was added to citrate as an energy source, but caramelization occurred during heat sterilization because of the alkaline pH.[18] The citrate and dextrose were thus sterilized separately and mixed before the blood was collected. In 1943, Loutit and Mollison[18] added citric acid, creating acid citrate dextrose (ACD) solution. This formulation decreased the pH, allowed sterilization without caramelization, and facilitated storage for up to 21 days. It was also noted that because of the decreased pH, the blood and preservative solution had to be mixed thoroughly during collection to avoid clot formation.[19] The most commonly used storage solution in the United States, CPDA-1, supplies 10.1 mmol per unit of glucose, compared with 9.4 and 8.1 mmol per unit in ACD-A and CPD storage solutions, respectively (Table 18–2). Most patients tolerate the glucose transfused. However, for many years, hyperglycemia seen during massive transfusion in orthotopic liver transplantation has been commonly attributed to the glucose contained in transfused RBCs.[20] A recent study of pediatric and adult patients questions this finding: 60 pediatric and 16 adult patients receiving orthotopic liver transplants were included in the study. Blood glucose levels in transfused and nontransfused patients were compared, and no difference was found between the two groups.[21]

Anticoagulation

Citrate has been used since the early 1900s as a stable, minimally toxic anticoagulant that also has preservative properties.[22] Citrate in preservative solutions also influences intracellular pH and provides buffering.

Citrate is part of the Krebs cycle of respiration and therefore occurs endogenously. It is metabolized by muscle, liver, and renal cortex and stored in bone. In massive transfusion, citrate has been considered to be a cause of cardiac arrhythmia because of its ability to decrease plasma ionized calcium through chelation, although clear evidence of toxicity resulting from hypocalcemia has been difficult to obtain. Citrate is metabolized rapidly, preventing systemic anticoagulation. However, certain conditions may place patients at risk for toxicity. Hypothermia, liver disease, and hypoparathyroidism are conditions in which patients may already have depressed ionized calcium or may not be able to metabolize the citrate rapidly.[23] Newborns without adequate calcium stores and immature livers may also be at risk. Because supplementation with intravenous calcium may be associated with its own toxicities, routine calcium administration is not recommended in massive transfusion.

Adenosine Triphosphate

The ATP content of pRBCs decreases with storage, from 4.18 μmol/g hemoglobin at collection in CPDA-1 to 2.40 μmol/g hemoglobin at 35 days of storage.[24] Changes in RBC shape and increased cell fragility have been noted in stored RBCs.[25] It was not until 1962 that a direct correlation was made between erythrocyte shape and ATP content.[26] The decrease in ATP with storage is associated with a change in erythrocyte shape from biconcave disc to spherocyte, as well as a decrease in membrane lipid content and an increase in cell rigidity. Therefore, ATP must be maintained during storage for appropriate posttransfusion survival of RBCs. The addition of adenine counteracts the loss of adenine groups and allows enough ATP for RBC survival.

2,3-Diphosphoglycerate

The concentration of erythrocyte 2,3-DPG in pRBCs also decreases with storage. The decrease is dependent on pH. In whole blood collected in CPDA-1, the pH decreases from 7.16 to 6.73 over 35 days as a result of lactic acid formation, and the 2,3-DPG concentration decreases markedly from 13.2 to 0.7 μmol/g hemoglobin.[24]

In the RBC, the glucose intermediate metabolite 1,3-DPG is transformed to 2,3-DPG by a mutase. The 2,3-DPG is then dephosphorylated to 3-phosphoglycerate by a phosphatase. The phosphatase is inactive at pH levels above 7.2 but is more active at the lower pH in older pRBCs, contributing to the decreased 2,3-DPG levels.[27]

Table 18–2 **pRBC Storage and Additive Solutions**

Substance Content (mmol/unit)	ACD-A*	CPDA-1*	CPD*	CP2D*	Adsol (AS-1)†	Nutri-cell (AS-3)†
Citrate	5.3	6.6	6.6	6.6	—	0.2
Phosphate	—	1.0	1.3	1.3

From Hogman CF. Preparation and preservation of red cells. Vox Sang 1998;74(suppl 2):177.

The function of erythrocyte 2,3-DPG is to bind to deoxyhemoglobin and facilitate oxygen transport. When 2,3-DPG binds to deoxyhemoglobin, the deoxyhemoglobin molecule is stabilized, and the equilibrium between deoxyhemoglobin and oxyhemoglobin shifts toward deoxyhemoglobin. This interaction shifts the oxygen-dissociation curve to the right, decreasing the oxygen affinity of hemoglobin and enhancing oxygen delivery to tissues.[28] Therefore, with decreased 2,3-DPG levels, the oxygen dissociation curve is shifted to the left, decreasing oxygen delivery to tissues.

Although it may be feared that transfused RBCs beyond a certain date of storage are of limited benefit to the patient, it has been shown that 2,3-DPG is rapidly regenerated in transfused RBCs, with nearly complete restoration after 1 day. In addition, in hypoxia, lactic acid is produced, decreasing the pH and thus shifting the oxygen-dissociation curve back to the right.[29] An increase in cardiac output also occurs with hypoxia, increasing oxygen delivery. Therefor, for most patients requiring transfusion, decreased 2,3-DPG is of little consequence. For the patient who is in shock and cannot increase cardiac output to compensate, the current preservative solutions may not be optimal because no added component is available to slow the decrease in 2,3-DPG levels.

Additive and Rejuvenation Solutions

In 1983 an RBC additive solution, Adsol (Baxter, Round Lake, Ill.), also referred to as AS-1, was approved for use. Adsol consists of adenine (to help maintain ATP during storage), dextrose, saline, and mannitol. It contains 60% more adenine and approximately 2.5 times as much glucose as CPDA-1.[30] The addition of mannitol prevents excessive hemolysis over the storage period.[31] The increased glucose allows an adequate supply of energy for the RBCs beyond 35 days, and blood stored with Adsol is outdated in 42 days (Tables 18–2 and 18–3).[8] This decreases the number of pRBCs lost because of outdating and is helpful in shipping and storing autologous blood.

One of the added benefits of this preservative solution is that the amount of plasma recovered from a unit of whole blood can be maximized. Whole blood is collected into a system of multiple closed bags containing CPD. The whole blood is then centrifuged for separation, and sufficient plasma is removed to raise the hematocrit to approximately 85%. Then 100 mL of Adsol preservative solution is added to the pRBCs, with a resultant hematocrit of 60% to 70%. Because the final hematocrit is about 62%, the Adsol-preserved pRBCs are less viscous. The lower viscosity results in potentially faster flow rates, which are beneficial in emergency situations.[32] A second commonly used additive solution, AS-3, contains sodium chloride, phosphate, adenine, and glucose and is used similarly to AS-1.

Other additive solutions have been investigated. A solution containing adenine, dextrose, mannitol, sodium citrate, ammonium chloride, and inorganic phosphate was studied.[33] Levels of ATP were higher in this test solution, compared with those in Adsol, over 84 days of storage. 2,3-DPG levels were higher in the test solution, but not significantly, and hemolysis was higher in the Adsol units. It was thought that the higher ATP concentration in the test solution was due to the ammonium or phosphate ions or both.[30] In vivo survival was demonstrated in a second study by using a modification of the previous test solution (less ammonium chloride). The 24-hour chromium-51 viability was superior to that of Adsol at 8 or 9 weeks of storage. Preparation for transfusion required removal of supernatant with one washing step.[34] This additive solution appears to be suitable for extending pRBC shelf life, but confirmatory studies are necessary.

Rejuvenation solutions can restore some intracellular ATP and 2,3-DPG lost during storage. The current FDA-licensed solution contains pyruvate, inosine, phosphate, and adenine. This solution may be added only to pRBCs prepared from whole blood collected in CPD or CPDA-1. It may be added at any point between 3 days after collection and 3 days after expiration. This solution is not intended for intravenous use, and pRBCs must be washed before administration or used when thawing frozen units.[8] Rejuvenation of units stored in AS-1 or AS-3 has also been studied.[35] In one experiment, rejuvenation of the AS-1 and AS-3 pRBCs resulted in above-normal levels of ATP after one treatment but suboptimal levels of 2,3-DPG. A second treatment raised the 2,3-DPG levels to normal. The authors suggested that this may be due to the increased adenine in the storage solutions; the conversion of 1,3-DPG to 3-phosphoglycerate is favored, decreasing 1,3-DPG availability to make 2,3-DPG.[35] Currently, only units stored in CPD or CPDA-1 may be used for rejuvenation.

Table 18–3 **42-Day Poststorage pRBC Characteristics after Resuspension in AS-3**

Characteristic	Prestorage	Poststorage
pH	6.8	6.4
ATP (μmol/g Hb)	4.1	2.9
DPG (μmol/g Hb)	9.0	0.3
Potassium (mEq/L)	2.4	63
Glucose (mg/dL)	608	402
Plasma Hb (mg/dL)	39	372
Hemolysis (%)	—	0.61

ATP, adenosine triphosphate; DPG, 2,3-diphosphoglycerate; Hb, hemoglobin; pRBC, packed red blood cell.

Modified from Holme S, Elfath MD, Whitley P: Evaluation of in vivo and in vitro quality of apheresis-collected RBC stored for 42 days. Vox Sang 1998;75:212–217.

Temperature

RBC concentrates must be stored between 1° C and 6° C.[8] Storage at this temperature slows RBC metabolism and facilitates extended storage in blood banks. Liquid blood storage in CPDA-1 allows a shelf-life of up to 35 days. Even at 4–8° C, significant chemical changes take place during the storage period that may have clinical consequences for some patients. These changes are collectively known as the *storage lesion.*

No clinically significant change occurs in the plasma levels of sodium and chloride. However, the plasma potassium increases nearly eightfold over 28 days.[36] At a temperature of 4–8° C, the sodium-potassium pump is essentially nonfunctional, and intracellular and extracellular levels gradually equilibrate. In addition, the hemolysis that occurs during the storage period results in increased potassium in the supernatant. However, because the total volume of plasma in pRBCs is low (approximately 70 mL), the total potassium burden is only about 5.5 mEq at product expiration. Therefore, the potassium load is rarely a clinical problem except in the setting of preexisting hyperkalemia and renal failure or for very sick neonates. In these situations, fresher units of RBCs or washed RBCs may be used.

Storage Containers

The use of vinyl plastic blood bags and tubing in transfusion medicine is advantageous in the collection, processing, storage, and dispensing of blood components. In the early 1970s, however, reports surfaced about the potential toxicity of blood stored in bags with di(2-ethylhexyl)phthalate (DEHP). DEHP, the chemical that allows the vinyl plastic to be pliable, is referred to as a plasticizer. DEHP is added in large quantities to the plastic, approximately 40% by weight. It is not bound to the plastic but is dissolved in it. As a result, DEHP can leak into blood stored in the container and be transfused along with the blood. In 1970, Jaeger and Rubin[37] reported that 5 to 7 mg of DEHP could be isolated per 100 mL of blood. In addition, two patients were found to have DEHP at levels ranging from 0.069 to 0.270 mg per gram dry weight of tissue. A more recent evaluation of the levels of DEHP in stored blood components found that as storage time increased, the amount of DEHP detected ranged from 6.8 to 36.5 μg/mL in RBC concentrates. Whole blood products had the highest DEHP levels, compared with RBC concentrates, irradiated RBC concentrates, FFP, and platelet products.[38] Concern over the potential toxic effects of DEHP in humans has fueled a great deal of research and much debate. DEHP, identified as a carcinogen in rats and mice,[39] is ubiquitous in the environment. It caused a form of shock lung leading to death when administered to rats in intravenous form,[40] caused testicular atrophy in rats given dietary doses,[41] and led to lung injury in dogs and baboons transfused with stored blood.[42]

Because of an association with hepatomegaly, DEHP has also been linked to potential hepatocarcinogenicity. Hepatomegaly has been shown to be caused by proliferation of cellular organelles called peroxisomes. Peroxisomes are involved in the β-oxidation of fatty acids, producing hydrogen peroxide, which has been suggested to be the causative agent in the carcinogenicity of DEHP.[43] With all of this information, however, no direct causal link has been established between DEHP and cancer in humans.

Because of the concerns about toxicity, alternative materials for blood-storage containers have been under investigation for some time. A study comparing another plastic, poly(ethylene-co-ethyl acrylate) (EEA), with polyvinyl chloride (PVC) containing DEHP[44] found that blood stored in EEA containers had higher plasma hemoglobin and greater susceptibility to osmotic lysis than did blood stored in PVC containers. When DEHP was added to EEA containers, blood stored in EEA containers without DEHP had greater RBC osmotic fragility than did blood in EEA with DEHP or PVC containers.

PVC plasticized with butyryl-*n*-trihexyl-citrate (BTHC) has been introduced in place of DEHP. Use of BTHC has not become widespread. Less BTHC than DEHP leaches into the bag contents, and excellent 24-hour posttransfusion RBC recovery occurs with minimal hemolysis.[45]

FROZEN RED BLOOD CELL CONCENTRATES

RBCs can be frozen for long-term storage, at least 10 years, and probably longer for certain indications.[8] After pRBCs are prepared from whole blood, they are treated with glycerol as a cryoprotective agent. Because glycerol binds water, the formation of ice spicules from the solvent water within the unit, which would damage the RBCs, is prevented.[46] Another theory concerning the efficacy of glycerol is that it prevents cellular hypotonicity or hypertonicity, which may enhance cell lysis. The blood of donors who have sickle cell trait is unsuitable for freezing because hemolysis occurs during routine deglycerolization.[47]

Of three methods of freezing RBCs,[48] the most common one in the United States is the high-glycerol (40% to 50%) method. A low-glycerol method exists, but it has several disadvantages: liquid nitrogen must be used for storage, and the metal containers in which the plastic blood bags are placed before freezing can cause explosions if the liquid nitrogen leaks.[49] With a third method, agglomeration, the cells are deglycerolized with a low-ionic-strength saline solution. The cells clump and sediment in the bag, after which the supernatant is removed, and the cells are washed.[50]

When the glycerol solution has been added, the cells are frozen and stored at −65° C or below in a suitable freezer or in liquid nitrogen with a gas-phase temperature below −120° C.[8] To be transfused, the cells must be thawed and deglycerolized. One of the initial drawbacks of the high-glycerol method was that the procedure of thawing and removing the glycerol had many practical limitations. A simpler method of processing these cells for transfusion was developed by Meryman and Hornblower.[50] Their method requires only two cycles of centrifugation, washing with saline, and resuspension with isotonic saline containing glucose.

The remaining product contains few white cells or platelets, and 99.9% of the plasma is removed by the extensive washing during processing.[51] More than 90% of the donor's RBCs are recovered.[52] The 24-hour posttransfusion survival has been shown to be 85% to 90%.[53]

Posttransfusion survival and oxygen-carrying capacity of RBCs are affected by the amount of time spent between donation, refrigeration, and freezing.[46] Frozen cells have been shown to maintain prefreezing ATP and 2,3-DPG levels. The standard is to freeze within 6 days of collection, before these factors become significantly depleted. When it is necessary to freeze older units, rejuvenation with a solution containing pyruvate, glucose, phosphate, and adenine can be used.[54]

The major advantage of frozen RBCs is that rare blood types, such as (Oh) Bombay, can be stored. Patients with rare phenotypes may make autologous donations that can be frozen for later use. Cells from autologous donors can also be frozen if more units are required than can be collected in the maximum 42-day liquid storage period or if surgery is postponed.

For patients who become alloimmunized to multiple clinically significant RBC antigens, frozen RBCs from donors with rare phenotypes are useful. Among these patients are multiply transfused patients with sickle cell anemia who have multiple alloantibodies. African-Americans frequently lack antigens found on most donor RBCs from whites. During blood drives targeting the African-American community for the benefit of such patients, it is helpful to phenotype these RBCs and freeze the more uncommon types.

Because 99.9% of plasma is removed in processing frozen RBCs, patients who may have adverse events related to plasma components may also benefit from the use of frozen RBCs. For example, immunoglobulin A (IgA)-deficient patients with anti-IgA antibodies may have anaphylactoid reactions

when exposed to donor plasma. In the past, patients who had multiple febrile nonhemolytic transfusion reactions that persisted despite removal of the buffy coat and treatment with medications also benefited from the more complete removal of cytokine-laden plasma and the leukoreduction that thawed frozen RBCs offered. Newer leukocyte reduction techniques have largely replaced this indication. Because of the high cost and cumbersome nature of freeze-thaw procedures, other more routine uses of frozen RBCs are difficult to justify. If a simpler means of preparation of frozen blood were available that avoided the limitations of the open systems now used, more widespread use could be envisioned.

CYTOMEGALOVIRUS-SERONEGATIVE RED BLOOD CELL CONCENTRATES

Cytomegalovirus (CMV) is a double-stranded DNA herpesvirus (human herpesvirus 5) that can be transmitted by transfusion. Forty percent to 100% of adults are seropositive for CMV, depending on socioeconomic status and geographic region.[55] Persistent and latent infection can result, as well as reactivation and reinfection. The first report of transfusion-transmitted CMV described a syndrome seen in patients 3 to 8 weeks after cardiopulmonary bypass. The syndrome consisted of fever, lymphocytosis, and splenomegaly.[56] A congenital syndrome including petechiae, hepatosplenomegaly, jaundice, and microcephaly has also been identified. Postnatal infection in children can cause hepatitis. In immunocompromised adults, infection with CMV can result in interstitial pneumonitis, hepatitis, encephalitis, gastroenteritis, thrombocytopenia, or leukopenia; in certain patients receiving transplants, these conditions are associated with a high fatality rate. In immunocompetent adults, fever and hepatitis may result, but most patients have an asymptomatic mononucleosis.[55]

Transfusion-transmitted CMV is of concern in immunocompromised patients. CMV-seronegative blood is often requested for CMV-negative bone-marrow transplant candidates or recipients, in utero transfusions, low-birth-weight premature infants of CMV-negative mothers, CMV-negative pregnant women, and rare cases of human immunodeficiency virus–positive, CMV-negative patients. CMV-negative recipients of solid organ transplants from CMV-negative donors are among the patients who may benefit but in whom the risk of using blood products not tested for CMV is not well established.[52]

The sites of CMV latency are thought to include CD34-positive progenitor cells and CD13- and CD14-positive monocytes.[55] Thus transfusion-transmitted disease can be mitigated by removal of leukocytes in the pRBCs. A study published in 1995 compared bedside leukoreduction and CMV-seronegative blood products in bone-marrow transplant recipients and suggested that filtration is an effective alternative to CMV-seronegative blood for the prevention of transfusion-transmitted CMV. A follow-up of 142 bone-marrow transplant recipients found that in 62 CMV-seronegative recipients of bone marrow from CMV-seronegative donors, supported with the use of leukocyte-reduced blood products, no documented CMV infection occurred.[57] The American Association of Blood Banks (AABB) has suggested that both approaches, leukocyte reduction and the use of CMV-seronegative blood, are essentially equivalent in the prevention of CMV transmission.[58]

LEUKOCYTE-REDUCED RED BLOOD CELL CONCENTRATES

Leukocyte-reduced RBCs are defined by the AABB as having less than 5×10^6 leukocytes in the final component. Early techniques of leukocyte reduction involved centrifugation, washing with saline, and removal of the buffy coat. A second-generation technique known as the spin-cool-filter method was introduced in the 1980s.[59] This method requires use of 1-week-old RBCs, which are centrifuged and then cooled for 4 hours to enhance microaggregate formation before passage through a microaggregate filter. Currently, filtration can be performed at the bedside or in the laboratory with attachable filters that reduce leukocytes more than 99.9% with less than 10% depletion of RBCs.[60]

Leukocyte-reduced RBCs are indicated primarily in the setting of repeated febrile nonhemolytic transfusion reactions. It was previously thought that these reactions were mediated only by antibodies to foreign leukocyte antigens.[61] Now increasing evidence suggests that cytokines produced by the leukocytes during storage also cause these reactions.[62,63] Prestorage leukocyte reduction has also been shown to reduce substantially the incidence of febrile nonhemolytic transfusion reactions.[64]

A second indication for leukocyte-reduced RBCs is the prevention of sensitization to human leukocyte antigens (HLAs) in bone-marrow transplant recipients and other patients who require frequent platelet transfusion. The Trial to Reduce Alloimmunization to Platelets (TRAP) study[65] demonstrated a reduction in alloimmunization in acute myelogenous leukemia patients who received leukocyte-reduced blood components. Platelet refractoriness, although low in the control group (16%), was reduced among patients receiving leukocyte-reduced products (7%).

As a third indication, CMV transmission is mitigated as compared with the transfusion of unscreened blood products[66–68] and may be comparable (as mentioned earlier), or better than the use of seronegative products. At the time of this writing, it is unclear whether using both leukoreduced, seronegative units is superior to using either alone. Last, the use of nucleic acid testing, though only in use on a research basis, may provide additional safety (see Chapter 46).

Finally, leukocyte-reduced RBCs may have another indication. The transfusion of allogeneic blood is thought by many scientists to be immunosuppressive, an effect termed transfusion-related immune modulation (TRIM). Several studies appear to document this effect, but some controversy remains. A correlation between pretransplantation allogeneic RBC transfusions and improved renal allograft survival has been known for many years.[69,70] Initial reports appeared before the availability of cyclosporine and other improvements in immunosuppression that made this phenomenon less clinically relevant. However, a subsequent study including patients receiving modern immunosuppressive regimens demonstrated that recipients of three unmodified allogeneic RBC transfusions had 90% 1-year and 79% 5-year graft survivals, compared with 82% and 70% 1- and 5-year survivals, respectively, for patients who received no transfusion, which suggests continued importance.[71]

Perioperative allogeneic RBC transfusion may also have an adverse effect on tumor recurrence.[72–74] The data on this effect are more controversial; Blajchman[75] observed that approximately 50% of the nonrandomized studies

indicate an adverse effect of transfusion on tumor recurrence. Patients with colorectal cancer who received perioperative transfusions were shown to have longer hospital stays than those who did not receive transfusion,[76] but the effect in this study was attributed to a higher incidence of postoperative infection. In surgical patients, perioperative transfusion may also predispose to bacterial infection. A dose-response relation appears to exist between transfusion and the probability of infection; transfusion is the best predictor of infection, over such factors as extent of trauma, degree of blood loss, and presence of wound contamination,[77] although confounding factors have not been eliminated in many studies.

The mechanism for these effects may be related to the transfusion of contaminating white blood cells. The donor white blood cells could cause a downregulation of cellular immunity, mediated by secretion of T-helper 2 cytokines and inhibitors (interleukin-4, interleukin-10, and transforming growth factor-β), with resultant inhibition of the T-helper 1 response.[78] The potential benefit of leukocyte reduction appears to be supported by reports that patients having colorectal surgery who received leukocyte-reduced RBC transfusions had fewer infections and shorter hospital stays than did those who received unmodified RBCs.[78] Animal studies also appear to support this theory. In rabbits inoculated with VX-2 tumor cells, those that received unmodified allogeneic RBC transfusions had significantly more pulmonary metastases than did those that received 99.8% leukocyte-reduced blood.[79]

An editorial concerning TRIM stated, "prestorage WBC reduction is an intervention that is virtually risk-free and that, except for its cost, has no down side … the decision to implement universal prestorage WBC reduction need not be delayed until further evidence of efficacy becomes available."[80] The suggestion that leukocyte-reduced RBCs decrease the unwanted immunosuppressive effects of transfusion may be further proof that conversion to a leukocyte-reduced blood supply enhances patients' safety.

In light of these indications for leukoreduced RBCs, many centers have moved to universal prestorage leukoreduction. Some hospitals, however, use a selective leukodepletion policy based on lack of direct convincing evidence that leukoreduction offers benefits to patients not in certain categories. Data in support of this practice is available from a prospective randomized trial, which showed no benefit to conversion to a universally leukodepleted inventory, except for specific indications, such as a reduction in febrile transfusion reactions.[81] The cited study did, however, show a trend toward increased safety with leukoreduced units and may have been underpowered. One of the pitfalls of selective leukodepletion is the difficulty of recognizing which patients require leukodepletion in complex clinical settings; in addition, this study did not address the potential adverse long-term consequences of CMV infection or alloimmunization in the recipients. Without a community standard for universal leukodepletion, patients in groups that do qualify for certain protocols may be overlooked and will not receive these components.[82] Based on these concerns, the authors feel that universal leukodepletion offers safety advantages for all patients and guarantees the receipt of leukoreduced blood in such cases in which the specific indication is not recognized or may not have yet occurred.

WASHED PRBCs

Washed RBCs are prepared with isotonic saline by either manual or automated methods. Automation is more efficient, resulting in loss of fewer RBCs with each wash cycle. Because washing takes place in an open system, the product must be used within 24 hours.

Washing RBCs removes plasma proteins, some leukocytes, and remaining platelets. This product is indicated for patients who have had recurrent severe allergic transfusion reactions that are not prevented by antihistamines. Recipient IgE antibodies to donor plasma proteins mediate these reactions. Washed RBCs are also indicated for IgA-deficient patients who have formed anti-IgA antibodies. In these patients, transfusion of blood products containing plasma with IgA can result in anaphylaxis.[83]

In patients with paroxysmal nocturnal hemoglobinuria (PNH), a rare disorder in which RBCs are unusually sensitive to complement lysis, transfusion of washed RBCs has been advocated to prevent hemolysis. However, a report by Brecher and Taswell[84] on 23 patients with PNH seen over a 38-year period appears to show that this is a needless practice.[84] A total of 431 RBC products (94 whole blood, 208 pRBCs, 80 leukocyte-reduced RBCs, 38 washed RBCs, 5 frozen RBCs, and 6 intraoperatively salvaged units) were transfused with only one episode of hemolysis after transfusion. This single event was associated with transfusion of group O whole blood to a group AB individual. Although the need for washed RBCs in PNH is questionable, this disorder is rare, and changing established transfusion protocols may not be justified.

IRRADIATED PRBCs

RBCs are commonly irradiated by using a cesium 137 source. A dose of at least 2500 cGy must be delivered to each unit, and quality-control standards have been published to ensure that this dose is achieved with blood bank irradiators.[85] After irradiation, storage time is decreased to a maximum of 28 days[8] because of shortened RBC survival and increased potassium leakage. Please see Chapter 28 for additional and detailed information.

The purpose of irradiation of cellular blood products in transfusion medicine is to inactivate immunocompetent lymphocytes. Irradiated RBCs are indicated for the prevention of transfusion-associated graft-versus-host disease in immunocompromised patients, a frequently fatal complication. Neonates, patients with hematologic malignancies, patients with aplastic anemia, bone-marrow transplant recipients, and patients with congenital immune deficiency are susceptible to transfusion-associated graft-versus-host disease.[86] Graft-versus-host disease is also a potential hazard of directed donation from first-degree relatives who share HLA haplotypes.[87] See Chapter 53 for additional information regarding this phenomenon.

Chapter 19

Fresh Frozen Plasma and Related Products

Robert L. Crookes • Christopher D. Hillyer

Component therapy has had a profound impact on the practice of transfusion medicine. The extraction of various constituents, including plasma, from whole blood has led to increased efficacy and economic utilization of the blood supply. When only the component that is needed is transfused, the patient is spared untoward effects of other blood components. Plasma, both in the circulation and for transfusion, contains a variety of organic and inorganic elements with therapeutic value as described subsequently. However, the isolation, purification, and preparation for injection or transfusion of some specific plasma constituents [e.g., factor VIII (FVIII), albumin, immunoglobulins] have limited the use of fresh frozen plasma (FFP) in clinical practice. The use of FFP (and related plasma components) is now reserved for conditions requiring therapy in which replacement of multiple plasma constituents is needed or for which the specific constituent is not commercially available in a purified injectable or transfusable form.

PHYSIOLOGIC ROLE OF PLASMA

Plasma is the aqueous component of blood in which cellular elements and macromolecules are transported throughout the body and other constituents are maintained in a dynamic equilibrium with the extravascular compartment. The composition of plasma is influenced by gender, age, diet, and other individual and environmental characteristics.[1,2] The major component of plasma is water, which constitutes approximately 85% to 90% of the plasma volume. The solute component constitutes 0.3 mol/L, of which about 30% is made up of proteins, with colloids, crystalloids, clotting factors, hormones, vitamins, and trace elements making up the rest. Normal human plasma has a density of 1.055 to 1.063 g/mL and a pH that varies between 7.33 and 7.43 with respective temperature changes between 37°C and 4°C.[3]

Although human plasma contains a multitude of substances including ionic and nonionic solutes, the practice of transfusion medicine has exploited plasma mainly for its protein content. It is estimated that human plasma contains more than 700 different proteins with various physiologic characteristics and functions. Although some 120 proteins have been isolated, only a few are available for clinical use. The most abundant plasma protein is albumin, with a concentration between 3500 and 5000 mg/dL. Albumin is responsible for maintaining colloid oncotic pressure and serves as a major transport protein for endogenous and exogenous substances. Plasma proteins with immunologic functions include the immunoglobulin (Ig) family, of which IgG (5 to 14 mg/dL) is the most abundant, and the complement components, of which C3 (1.2 mg/dL) predominates quantitatively. In addition, plasma proteins include those involved in maintaining normal rheologic properties of blood (e.g., coagulation and fibrinolytic proteins).[4–6]

PLASMA COLLECTION, QUALITY, AND PROCESSING

Plasma can be obtained through centrifugation of whole blood, single-donor plasmapheresis, or as a by-product of cytapheresis [e.g., platelet or red blood cell (RBC); *concurrent plasma*]. One unit of plasma is defined as the amount of plasma obtained from centrifugation of 1 unit of whole blood, and it usually contains 180 to 300 mL. When plasma is obtained through single-donor plasmapheresis, the amount may be 2 to 3 times greater than that obtained from whole blood processing (500 to 800 mL). Most plasma that will be used as FFP or FP24 (see later) is collected from whole blood (or equivalent) donors, and thus donor safety, screening and testing measures apply.

The rapidity with which plasma is collected and stored determines its quality and subsequent use.[7,8] Thus several plasma products are available at various centers. Single-donor plasmapheresis can produce *source plasma* (or single-donor plasma) when it is stored at or below −18°C at variable times from its collection. Plasma prepared from whole-blood or apheresis collections and stored frozen within 8 hours of its collection (at −18°C or colder) is called *fresh frozen plasma (FFP)*. Plasma separated from whole-blood donations and frozen below –18°C within 24 hours of collection (FP24) shows good retention of relevant coagulation factor activity. However, compared with historic data on FFP frozen within 8 hours, fibrinogen, FV, FVIII, and FXI were shown to be reduced in FP24 by 12%, 15%, 23%, and 7%, respectively.[9] This may be significant in certain clinical circumstances, such as in the treatment of neonates with coagulopathies. In general, however, FFP and FP24 are used interchangeably in many facilities throughout the United States, especially at large tertiary care hospitals with busy level 1 trauma centers.[10] *Thawed plasma* is prepared in a closed system from FFP or FP24. Centrifugation or sedimentation of whole blood can also produce *recovered plasma*, which is obtained from a whole-blood donation: *liquid plasma*, when collected and stored refrigerated within 5 days of the expiration date of whole blood: *Cryo-poor plasma* (*cryosupernatant plasma; CSP*), which is the plasma product remaining after the cryoprecipitate fraction is extracted from FFP through cold precipitation.

Both source plasma and recovered plasma may be used in the manufacture of various plasma derivatives. Source

plasma can also be administered as component therapy, whereas recovered plasma, because of the less-stringent conditions of collection, processing, and storage, does not meet the standards for coagulation factor concentrations and therefore is not used as component therapy. Liquid plasma is no longer used in the United States. *Donor retested plasma (FFP-DR)* is FFP, or FP24, which has been placed in "quarantine" and released for transfusion only after the donor has donated a subsequent blood donation, which has been tested ("retested") and found to be negative for markers of transfusion-transmissible infection. The quarantine period is at least 56 days. FFP-DR is considered a safer product, as subsequent testing of the blood donor is expected to detect and eliminate plasma donations that are in an infectious window period.[11]

Virally inactivated plasma is pooled plasma subjected to a solvent-detergent process and is termed *solvent-detergent plasma* (SD plasma). This method is highly efficient at inactivating viruses by using a combination of organic solvent, tri(*n*-butyl)phosphate (TNBP), and a nonionic detergent, Triton X-100. The SD method is virucidal against lipid-enveloped viruses, including human immunodeficiency virus (HIV) types 1 and 2, hepatitis viruses (HBV, HCV, HGV), human T-cell leukemia/lymphoma virus (HTLV) types I and II, vesicular stomatitis virus, Sindbis virus, and Sendai virus, but does not inactivate parvovirus or hepatitis A virus.

SD plasma is pooled from approximately 2500 donors, which results in a standard unit of 200 mL of SD plasma with a coagulation factor profile similar to that of FFP.[12–16] In part due to its cost, and in part due to the lack of availability of virally inactivated RBC and platelet units, SD plasma is not used in the United States.

SD plasma is, however, not simply a virally inactivated equivalent of FFP.[17] Levels of factor V, factor VIII, protein S, antiplasmin, and antitrypsin are lower in SD plasma, and this is of potential clinical significance.[17–20] The serpin-type serine proteinase inhibitors such as antiplasmin, antitrypsin, and antithrombin, have a flexible reactive-site loop that can convert from the active conformation to the inactive latent or polymerized conformations when exposed to heat or detergents or both. Comparisons of conformational stability and inhibitory activity have shown that, in SD plasma, virtually 100% of antiplasmin and approximately 50% of antitrypsin are in either the latent or polymerized conformation and lack inhibitory activity, whereas in FFP, only the active conformation is present.[17] Leukocyte depletion of FFP may also result in losses of coagulation factor activity and in increases in markers of coagulation activation, depending on the type of filter used. This is unlikely to be clinically significant unless subsequent processing of plasma (such as pathogen inactivation) results in further losses of coagulation factors.[21]

CLINICAL CONSIDERATIONS

In clinical practice, FFP has been used as an exogenous source of proteins, specifically albumin, immunoglobulins, coagulation factors, and certain protease inhibitors. With the development of the fractionation method of Cohn and colleagues[22] and the consequent capability to administer individual plasma components, the use of FFP has been reserved for situations in which it is necessary to replace either multiple plasma constituents (e.g., multiple factor deficiency) or a plasma constituent not yet isolated. The randomized controlled trial evidence base for the clinical use of FFP is, however, limited.[23] Indications and contraindications are listed in Table 19–1.

THE USE OF FFP IN THE MANAGEMENT OF COAGULOPATHIES

Patients with a known underlying coagulopathy, as ascertained by an increase in the prothrombin time (PT >16 seconds) or partial thromboplastin time (PTT >55 seconds) exceeding 1.5 to 1.8 times the control value, have an increased risk for clinically significant bleeding. In these patients, administration of FFP has decreased the risk of bleeding and reduced or stopped active bleeding. Although FFP contains all coagulation factors at normal plasma concentrations, it must be recognized that its administration in physiologically tolerable quantities results in only a 20% to 30% increase in the levels of coagulation factors.

Coagulopathy of Liver Dysfunction

The liver is essential in maintaining normal hemostasis. First, as the principal site of protein synthesis, it supplies the majority of proteins involved in the coagulation and fibrinolytic

Table 19–1 **Fresh Frozen Plasma: Indications and Contraindications**

Indications	Contraindications
Coagulopathies[23]	Volume expansion
Liver disease[24–45]	Immunoglobulin replacement
Acute hepatocellular injury	Nutritional support
Chronic hepatic dysfunction	Reconstitution of pRBCs
Hepatic surgery[29–44]	Wound healing
Congenital factor deficiency*[46–50]	
Warfarin-induced coagulopathy[50–58]	
Dilution-induced coagulopathy[59–70]	
Disseminated intravascular coagulopathy[52,71–76]	
Replacement of other factor(s)[23]	
Plasma infusion or exchange[76–104] (TTP, HUS, HELLP)	
C1-esterase inhibitor deficiency*[105–107]	
Fluid replacement in TPE[108] (Refsum disease, frequent TPE, coagulopathy)	

*When factor concentrates are not available.

HELLP, hemolysis, elevated liver enzymes, and low platelets; HUS, hemolytic-uremic syndrome; pRBCs, packed red blood cells; TPE, therapeutic plasma exchange; TTP, thrombotic thrombocytopenic purpura.

pathways and their regulators (except FVIII, von Willebrand factor [vWF], tissue plasminogen activator, and plasminogen activator inhibitor). Second, a process important in the normal function of certain coagulation proteins (e.g., prothrombin; FVII, FIX, and FX; proteins C and S), vitamin K–dependent γ-carboxylation of glutamic acid residues, takes place in the liver. Third, the hepatic reticulum endothelial system is also involved in the clearance of activated coagulation factors, activation complexes, and fibrin and fibrinogen degradation by-products. Therefore the coagulopathy associated with hepatocellular injury has a complex pathogenesis including ineffective protein synthesis, consumption of coagulation factors and inhibitors, and impaired clearance of activated coagulation complexes.[24–26] In addition, end-stage liver disease is associated with a variable degree of thrombocytopenia secondary to hypersplenism[27] and a multifactorial thrombocytopathy.[28]

Impairment of hemostasis may also be encountered in hepatic surgery, including partial hepatic resection,[29] orthotopic liver transplantation (OLT), and peritoneovenous or LeVeen shunt placement. The coagulation disorder most frequently observed in these situations is acute and chronic disseminated intravascular coagulopathy (DIC) with a predominant fibrinolytic component.[30,31] The coagulopathy associated with OLT is usually more severe because of the underlying coagulopathy predating the transplantation, the profound hyperfibrinolysis characterizing the posttransplantation anhepatic phase, and, in some instances, the coagulopathy induced by massive transfusion during surgery.[32–35] The number of units of blood products transfused during OLT operations has decreased significantly for reasons that include the use of aprotinin to block fibrinolysis and the selective use of the thromboelastogram to monitor coagulation intraoperatively.[36] In liver transplantation patients, whole blood, when compared with component therapy (RBCs and FFP), has been reported to provide equally effective replacement therapy for blood loss and is associated with fewer donor exposures.[37] Plasmapheresis using FFP, or FFP and albumin (50%), as replacement fluid may provide an effective treatment option for primary hepatic allograft nonfunction immediately after liver transplantation and may obviate the need for retransplantation.[38]

It is well recognized that patients manifesting coagulopathy associated with liver disease or hepatic surgery are at increased risk for bleeding, especially during invasive procedures (e.g., liver biopsy, paracentesis). Therefore, FFP, either alone or in conjunction with other products (e.g., platelets, prothrombin complex, or antithrombin III concentrate), has been used to control active bleeding and to decrease the risk of bleeding complications during invasive procedures.[39–43] The efficacy of FFP in these situations is assessed clinically because laboratory evidence such as normalization of PT or PTT or improvement of the thromboelastogram may be lacking with the administration of usual quantities of FFP.[39,43,44] Recombinant activated factor VII (rFVIIa) is an antihemophilic factor that has shown promise in treating coagulopathy in liver disease and, in conjunction with FFP, is effective in transiently correcting laboratory parameters of coagulopathy in patients with fulminant hepatic failure.[45] In these patients, it facilitates the performance of invasive procedures and is associated with less frequent anasarca compared with conventional therapy.

Congenital Coagulation Factor Deficiency

The introduction of specific coagulation factor concentrates has limited the use of FFP. Currently, FFP is indicated for patients with rare familial isolated factor deficiencies (e.g., FV and FXI deficiency) for which no factor concentrate is commercially available.[46–49] In combined FV-FVIII deficiency, FFP is the only source of FV, and either FFP infusions or therapeutic plasma exchange (TPE) with FFP has been used to treat bleeding episodes. Congenital combined vitamin K–dependent factor deficiency can be treated with prothrombin complex concentrates, FFP, or occasionally high doses of vitamin K.[50] Dosages and schedules of FFP administration for congenital factor deficiencies and possible alternatives are listed in Table 19–2.

Warfarin-induced Coagulopathy

Vitamin K is a cofactor in the γ-carboxylation of the terminal glutamic acid residues of certain coagulation (e.g., factors II, VII, IX, and X) and regulatory (e.g., protein C and S)

Table 19–2 **Uses of FFP in Congenital Factor Deficiencies**

Deficient Factor	Half-life (hr)	FFP Dose	Hemostatic Plasma Level	Alternative Therapy
Prothrombin (FII)	72	15–20 mL/kg, followed by 3–6 mL/kg q 12–24 hr	>30%	PE with FFP Prothrombin complex concentrates*
Factor V (FV)	36	15–20 mL/kg, followed by 3–6 mL/kg q 12–24 hr	>25%	FFP infusions or TPE with FFP
Factor VII (FVII)	3–6			Prothrombin complex concentrates*
Major bleed		15–20 mL/kg followed by 5–10 mL/kg q 6–12 hr	15%–25%	FVII concentrates†
Mild bleed		5–10 mL/kg q 8–12 hr	5%–10%	
Factor X (FX)	40	15–20 mL/kg, followed by 3–6 mL/kg q 24 hr	10%–15%	Prothrombin complex*
Factor XI (FXI)	80	15–20 mL/kg, followed by 3–6 mL/kg q 12 hr	30%–40%	Cryosupernatant
Factor XIII (FXIII)	9 days	3–6 mL/kg q 4–6 wk	5%	Cryoprecipitate (1 U/10–20 kg q 3–4 wk) FXII concentrate†

FFP, fresh frozen plasma; FII, factor II; TPE, therapeutic plasma exchange.

proteins. This posttranslational modification of the coagulation proteins is essential for their binding to phospholipid surfaces through calcium and the subsequent formation of activation complexes.[51] By interfering with the recovery of the active form of vitamin K, warfarin or 4-hydroxycoumarin blocks the γ-carboxylation of these coagulation proteins, rendering them inactive.

Over-anticoagulation from excessive effects of warfarin can be reversed by a range of measures.[52] From the most mild to the most severe circumstances, these are withdrawing warfarin, giving vitamin K orally or parenterally, transfusing FFP, or administering prothrombin complex concentrate (FII, FVII, FIX, and FX or separate infusions of FII, FIX, and FX concentrate plus FVII concentrate or FFP).[53] The dose of vitamin K used to reverse over-anticoagulation depends on the international normalized ratio (INR).[54] Prothrombin complex concentrate (PCC), or FFP, should be used in such situations involving trauma, emergency surgical procedures, or active bleeding.[55,56] FFP is recommended only if major bleeding occurs and PCC is not available.[56,57] Makris et al.[57] showed that FFP contains insufficient concentrations of vitamin K factors to reverse warfarin effects completely. Treatment with FFP (15 mL/kg) and intravenous vitamin K (5 mg) will partially reverse anticoagulation, although the levels of individual factors will typically remain less than 20%, and larger doses should be given if possible. FFP should never be used for the reversal of warfarin when no evidence of severe bleeding exists.[56] Vitamin K and FFP often fails to achieve the desired correction of coagulopathy in urgent neurosurgical settings such as spontaneous or traumatic intracranial hemorrhage. A single dose of rFVIIa (120 mg/kg) was shown to provide rapid reversal of anticoagulation and should be considered when urgent neurosurgical intervention is required.[58]

Dilutional Coagulopathy

The replacement of one blood volume in 24 hours with packed red blood cells (pRBCs) and crystalloid or colloid solutions is defined as massive transfusion.[59] Leslie and Toy[60] found that massively transfused patients manifest a profound hemostatic disorder, as demonstrated by prolonged PT and PTT to twice control values and thrombocytopenia less than $50 \times 10^6/\mu L$, which are only in part due to hemodilution.[61,62] Although the number of units transfused, the degree of PT or PTT prolongation, and bleeding tendency are poorly correlated,[63,64] Ciavarella and colleagues[61] reported that increases in PT or PTT greater than 1.5 to 1.8 times control values are associated with decreases in some coagulation factors (e.g., fibrinogen, FV, FVIII) to below minimal hemostatic levels. Therefore the preceding laboratory changes, when associated with clinically significant coagulopathy, should be treated with FFP. Resuscitation from hemorrhagic shock can be successfully managed by restoration of blood loss with crystalloid and blood, and with FFP added to maintain coagulation proteins. In a canine hemorrhagic shock model, FFP has been demonstrated to prevent the reduction of coagulation factor levels, and unexpected postoperative bleeding has been observed in humans after the abandonment of routine supplementation of FFP for hemorrhagic shock.[65] Leukocyte adhesion to endothelial cells may contribute to microcirculatory disturbances during severe shock syndromes. When incubated with FFP, neutrophil adhesion to endothelial cells is decreased in vitro,[66] and the administration of FFP may attenuate the inflammatory response of endothelial cells in clinical situations in which dilution of plasma is found. In general, FFP should be considered when more than 50% of the blood volume has been replaced, and it is mandatory when more than 120% to 150% of the blood volume has been replaced with pRBCs or colloid solutions, or both, within a 24-hour period. In addition, platelets should be maintained above $50 \times 10^6/\mu L$ with transfusion of platelet concentrates, and other blood products (e.g., cryoprecipitate, specific factor concentrates) may be considered for replacement of coagulation factors when the volume of FFP becomes excessive.[67–69] The use of FFP in the pump prime in infants undergoing cardiopulmonary bypass surgery has been shown significantly to limit dilutional hypofibrinogenemia, decrease the transfusion of cryoprecipitate after bypass, and decrease overall exposure to blood products.[70]

Disseminated Intravascular Coagulopathy

Acute DIC is clinically characterized by a combination of diffuse microvascular hemorrhage and thrombosis. Abnormal activation of the coagulation cascade and thrombin generation leads to the consumption of procoagulant factors and platelets. All coagulation factors become depleted, but particularly fibrinogen, FV, FVIII, and FXIII.[52] Hyperfibrinolysis secondary to widespread fibrin deposition further exaggerates the coagulation factor consumption. A wide variety of disorders may lead to DIC, including sepsis, liver disease, trauma, obstetric complications, leukemia, metastatic malignancy, hypotension, and hypoperfusion.[71]

Because of the heterogeneous group of disorders that can trigger DIC, the gamut of clinical manifestations, and the lack of controlled clinical studies, the management of DIC is somewhat controversial. Therapy should be individualized and directed concomitant with the underlying disorder and the predominant clinical manifestation (e.g., hemorrhagic versus thrombotic diathesis). Component therapy, with platelet concentrates, FFP, or cryoprecipitate, should be considered in patients with prolonged PT and PTT and active bleeding or undergoing an invasive procedure. FFP should be administered at a dose of 10 to 15 mL/kg and its effect assessed clinically and with frequent PT-PTT measurements (every 6 hours). In patients with end-stage liver disease and DIC, FFP infusions may not correct PT-PTT abnormalities, and clinical responses may vary. Antifibrinolytic agents (e.g., ε-aminocaproic acid or tranexamic acid) in combination with heparin may be useful in patients with active bleeding who do not respond to coagulation factor replacement with FFP or cryoprecipitate and heparin infusions.[71,72] In clinical situations in which the thrombotic diathesis predominates (e.g., purpura fulminans), a trial of intravenous heparin with antithrombin III (AT-III) replacement may be appropriate.[73] Initial studies have demonstrated some benefit for the use of activated protein C concentrates in patients with purpura fulminans[74] and in those with DIC associated with meningococcemia,[75] although further studies are needed to confirm these results.

THE USE OF FFP AS REPLACEMENT OF OTHER FACTORS

Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura (TTP) is a clinical entity characterized by microangiopathic hemolytic anemia,

thrombocytopenia, fever, and varying degrees of renal and neurologic dysfunction. Plasma exchange can induce remissions in approximately 80% of patients with idiopathic TTP; however, when thrombotic microangiopathy is associated with cancer, certain drugs, infections, or tissue transplantation, it carries a much worse prognosis.[76] The pathogenesis of idiopathic TTP has been shown, in many cases, to be due to an acquired autoimmune deficiency of a plasma metalloprotease, ADAMTS13 (a disintegrin and metalloproteinase with thrombospondin type 1 motif).[77–79] ADAMTS13 is a von Willebrand factor-cleaving protease (vWF-cp) responsible for the continuous degradation of ultralarge von Willebrand factor (ULVWF) multimers released from endothelial cells. Normally, ADAMTS13 cleaves ULFWF multimers within growing platelet aggregates, under flowing conditions, and this limits platelet thrombus formation. Plasma levels of vWF regulate ADAMTS13,[80] and the rate of VWF proteolysis is greater for blood group O VWF than for non-O VWF.[80,81] If ADAMTS13 is absent, either congenitally or because of acquired autoantibodies, platelet-rich microvascular thrombosis proceeds unchecked, and TTP ensues.[76,82,83] Severe deficiency of ADAMTS13 activity has been shown to define a distinct population of thrombotic microangiopathy patients.[84]

Plasma exchange is effective therapy for idiopathic TTP, probably because it replenishes the deficient ADAMTS13 and removes some of the pathogenic autoantibodies and endothelium-stimulating cytokines. Advances in assay methods should facilitate routine laboratory testing of ADAMTS13 for patients with thrombotic microangiopathy.[76,85,86] Severe ADAMTS13 deficiency is specific for idiopathic TTP and identifies a subgroup of patients with a high likelihood of response to plasma exchange. High-titer ADAMTS13 inhibitors correlate strongly with a high risk of relapsing disease. Patients with normal ADAMTS13 activity have a much worse prognosis, although many factors probably contribute to this difference.[76]

Infusion of FFP replaces the deficient or defective[87] metalloprotease, and therapeutic plasma exchange (TPE) with FFP or cryosupernatant removes much of the IgG metalloprotease inhibitor and simultaneously provides functional metalloprotease. The intrinsic VWF-cleaving protease activity of plasma-derived products correlates with their clinical efficacy.[85,88] VWF-cp activity is normal in FFP, CSP, and in virally inactivated components treated with methylene blue/light or by the solvent detergent process.[89] Current standard therapy for TTP is TPE with FFP as replacement fluid.[90–92] All patients do not respond initially to TPE with FFP, and in these recurrent or refractory TTP cases, the use of cryosupernatant plasma (CSP) lacking ULVWF multimers has been effective.[91–97] In the initial treatment of TTP in adults, the efficacy of FFP, compared with cryoprecipitate poor plasma, appears to be the same.[98] Other prospective studies have not shown an apparent advantage to the use of CSP in TTP.[99] Methylene blue–photoinactivated plasma seems to be less effective than FFP,[100,101] and reduced protein S activity in SD plasma may predispose to venous thromboembolism, especially if infused in large volumes.[89] A few patients with TTP have responded to simple infusions of FFP,[92,94,95] particularly patients who are HIV positive with a dominant microangiopathy.[102]

The standard therapy for TTP is daily exchanges with FFP or cryosupernatant replacing 1.0 to 1.5 plasma volumes. Plasma exchanges should be commenced at presentation and ideally within 24 hours of presentation.[103] The premature omission of a single plasma exchange may be associated with exacerbation. The total number of TPEs is dependent on the clinical response, and the daily schedule is continued until the serum lactic acid dehydrogenase is normal and the platelet count is greater than $100 \times 10^6/\mu L$ and continues to rise without the aid of TPE. A twice-daily (every 12 hours) schedule of TPE may be used in cases in which the patient's status is deteriorating despite an adequate daily regimen. The average number of TPEs necessary to achieve remission is approximately 16 procedures,[104] and more than 90% of patients have achieved clinical remission within 3 weeks of initiation of TPE.

C1-Esterase Inhibitor Deficiency

Deficiency of C1-esterase inhibitor, an important regulator of the complement system, is inherited in an autosomal dominant manner. Clinical manifestations of hereditary angioedema include swelling of the subcutaneous tissue and mucosa of the aerodigestive tract, leading to acute respiratory distress.[105] Replacement therapy with FFP infusions has been used during acute episodes of respiratory distress and before surgical interventions. C1-esterase inhibitor concentrates are available in Europe and will eventually replace the use of FFP in this rare condition.[106,107]

Fluid Replacement in TPE

In general, the volume of replacement fluids used in TPE is equal to the plasma volume removed, and for most situations, colloid or crystalloid solutions, or both, are acceptable fluid replacement. In addition to clinical conditions in which plasma is specifically indicated (e.g., TTP, Refsum disease), a few situations exist in which the use of FFP with TPE is preferred. Plasma exchange with FFP is indicated in all patients with significant underlying coagulopathy, including DIC, liver disease, and circulating anticoagulant, as well as in patients with iatrogenic coagulopathy, as observed in patients undergoing multiple TPEs within a short time.[108]

Investigational Uses of FFP

Coagulation factor replacement through the use of FFP, either as simple infusions or with plasma exchange, has been explored in fulminant meningococcemia,[109,110] in acute renal failure in the context of multiorgan failure,[111] and in the syndrome of hemolysis, elevated liver enzymes, and low platelets (HELLP).[112] FFP has been used successfully in the treatment of resistant, life-threatening angioedema due to an angiotensin-converting enzyme (ACE) inhibitor.[113]

PRACTICAL CONSIDERATIONS IN THE USE OF FFP

Although FFP is readily available for use in clinical practice, it must be recognized that its administration is not without risk. Although FFP contains albumin, coagulation proteins, immunoglobulins, and nutrients, no justification exists for its use in situations in which alternative therapy is safer and more efficacious. Therefore crystalloid or fractionated albumin solution is preferred to FFP for volume expansion in hypovolemic shock. A systematic review of randomized

controlled trials of albumin administration in critically ill patients[114] concluded, however, that there was no evidence to indicate that albumin administration reduces mortality in critically ill patients with hypovolemia, burns, or hypoalbuminemia. In conditions involving a specific coagulation factor deficiency, including hemophilia A, replacement therapy with specific coagulation factor concentrates or recombinant proteins (e.g., FVIII) is recommended. Prophylactic replacement therapy with immunoglobulin fraction and the use of approved parenteral solutions to enhance the nutritional status of debilitated patients are also currently recommended alternatives to FFP. The efficacy of FFP in other clinical situations should be determined through clinical trials.[23]

The volume and schedule of FFP administration depend on the clinical situation for which it is intended and the patient's volume tolerance. The most common indication for the use of FFP is as a coagulation factor replacement, and the desired hemostatic level as determined by the specific coagulation factor level, PT or PTT, or clinical assessment should guide the dose, frequency, and duration of administration. It should also be noted that FFP requires 20 to 30 minutes to thaw, and subsequently the labile coagulation factors (FV, FVIII) decrease gradually (adequate for 24 hours after thawing). FFP should be thawed in a controlled environment between 34° C and 40° C. Thawing at higher temperatures may result in markedly decreased coagulation factor activity.[115] Therapy should be coordinated with the blood bank, especially when multiple FFP infusions are anticipated (e.g, supportive therapy in massive transfusion, during OLT). FFP contains isohemagglutinins, and therefore an ABO-compatible product should be administered. AB plasma may be used in cases in which the recipient's blood group is not known at the time of administration. Compatibility testing is not routinely performed.

For the use of FFP in mild to moderate coagulopathies (e.g., liver disease, DIC), it is recommended that a usual dose of 10 to 15 mL/kg be infused as rapidly as tolerated by the patient. The calculated dose in milliliters is used to determine approximately the whole number of units of FFP, knowing that a unit of FFP is 180 to 300 mL and a unit of SD plasma is 200 mL. The frequency and duration of FFP therapy depend primarily on the clinical response. Observed increments in coagulation factor levels have been shown to correlate with the dose of FFP, and in critically ill patients, higher doses (30 mL/kg) should be considered.[116]

In massive transfusion or during OLT, communication with the blood bank is essential to reserve sufficient quantities of FFP and ensure timely administration. In general, when more than 10 units of pRBCs has been transfused and abnormal hemostasis is observed, infusion of 4 units of FFP is recommended. To maintain coagulation factors above a critical hemostatic level, 4 units of FFP should be infused for every 6 units of pRBCs transfused thereafter. If the desired hemostasis is not achieved with this regimen, additional products may be considered, including cryoprecipitate, rFVIIa, AT-III concentrate, or prothrombin concentrate.

ALTERNATIVES

Many factor concentrates, including FVIII, prothrombin complex concentrate, activated FIX complex, recombinant factor VIIa, and AT-III, have been made available for clinical use, and a few others are at the investigational stage (e.g., C1-esterase inhibitor). Thus the use of FFP is limited to situations in which no specific therapeutic alternative exists.

POTENTIAL ADVERSE REACTIONS

Although FFP is considered an infrequent cause of major adverse reactions, the complexity of plasma proteins, the heterogeneity of its immunoglobulin content, and factors related to its processing and storage have the potential to cause a wide range of reactions with various pathophysiologic mechanisms (Table 19–3). Allergic reactions of variable degree, ranging from mild urticarial reactions to anaphylaxis and cardiopulmonary arrest, may be observed with FFP infusions. These reactions may be related to the immunologic differences between donor and recipient or to the processing and storage of plasma.

Patients with IgA deficiency who have anti-IgA antibodies (usually IgE) are at high risk for acute and potentially fatal allergic reactions when exposed to FFP containing IgA. Patients known to be IgA deficient should receive IgA-deficient plasma, available through the national registry.[117] High titers of an alloantibody in the donor plasma may induce a variety of clinical syndromes, depending on the specificity of the antibodies. When plasma contains reaginic antibodies to foreign antigens, an allergic-type reaction may ensue. Conversion to a positive direct antiglobulin test or even hemolysis can occur when plasma contains antibodies directed against RBCs (e.g., ABO isoantibodies). If FFP of the same ABO group is not available, FFP of a different ABO group may be transfused, provided that it does not possess high-titer anti-A or anti-B activity. Group O FFP should not be used in infants or neonates who are not group O because the relatively large volumes can lead to passive immune hemolysis.[52]

Less often, febrile allergic reactions may be due to undesirable contaminants in the donor plasma. The risk of exposure

Table 19–3 Potential Adverse Reactions to FFP

Immunologically mediated:
Alloimmunization: Rh1(D), other RBC antigens
Allergic reactions: IgA deficiency
Transfusion-related acute lung injury (TRALI): leukoagglutinins
Reaginic antibodies to exogenous antigens
Alloantibodies to platelets
Immunomodulation/immunosuppression
Transfusion-associated graft-versus-host disease (TA-GVHD)
Related to plasma contaminants:
Donor specific: medications, infectious
Processing/storage specific: cytokines, anaphylatoxins, plasticizers, preservatives
Related to infectious contaminants:
Bacterial contaminants
Viral contaminants
Leukocyte-associated: CMV, HTLV I/II
Non–leukocyte-associated: HIV, HBV, HCV, HAV, EBV, HHV-8, prions
Related to physiochemical characteristics:
Volume overload
Hypothermia

CMV, cytomegalovirus; EBV, Epstein-Barr virus; HAV, hepatitis A virus; HBV, hepatitis B virus; HHV, human herpesvirus; HIV, human immunodeficiency virus; HTLV, human T-cell lymphotropic virus; RBC, red blood cell.

to donor-specific contaminants such as infectious agents and medications has been reduced considerably by careful donor screening. Febrile nonhemolytic reactions may also be related to the quality of plasma after processing, including activation of proteolytic enzymes (e.g., kinins), generation of cytokines (e.g., interleukins-1, -6, and -8, and tumor necrosis factor) and anaphylatoxins (e.g., C3a, C5a), and the presence of preservatives and plasticizers.[118–121]

Transfusion-related Acute Lung Injury

Transfusion-related acute lung injury (TRALI) is an uncommon complication of allogeneic blood transfusion characterized by acute respiratory distress, severe hypoxemia, hypotension, and fever. Radiographic investigations typically reveal bilateral pulmonary infiltrates. Clinical signs and symptoms usually manifest within 6 hours of transfusion.[122–124] Both immunologic and nonimmunologic mechanisms have been postulated in the pathogenesis of TRALI. It has been hypothesized that significant numbers of TRALI cases are the result of two insults. The first, related to the clinical condition of the patient (e.g., in a setting of surgery, trauma, or severe infection) causes neutrophils to be "primed" but not activated, and the second, to the infusion of biologic-response modifiers such as biologically active lipids, cytokines, or leukoagglutinating alloantibodies within the blood component transfused.[123–127] It is unlikely, however, that biologically active lipids are responsible for all cases of TRALI because they have not been shown to be present in FFP, even though the transfusion of FFP has been linked to many cases of TRALI.[123,128–130] Whereas pathogenic alloantibodies are typically of donor origin, in fewer than 10% of cases, the alloantibodies may be of recipient origin, directed against donor-specific leukocyte alloantigens.[131,132] The alloantibodies usually thought responsible for TRALI have been identified as antigranulocyte, antihuman leukocyte antigen (anti-HLA), or anti HLA-DR antibodies,[122,128–132] although some have also been reported to be caused by antilymphocyte, antimonocyte,[133–136] or anti-immunoglobulin alloantibodies.[131,137,138] Alloantibodies to HLA class I and class II antigens have been detected in approximately 22% of blood components tested.[139] These antibodies may also pose a risk to transplant patients requiring transfusions by promoting allograft dysfunction or loss. Because of the higher frequency of alloantibodies in multiparous women,[140] the Blood Service in the United Kingdom has elected only to use plasma from male blood donors for the preparation of FFP. Pooled, SD plasma has been shown have undetectable levels of HLA antibodies.[141,142]

Leukocyte-associated Adverse Reactions

FFP has long been considered an acellular blood product with an infinitesimally small risk of leukocyte-associated complications, including transmission of cell-associated infections, alloimmunization, immunosuppression, or transfusion-associated graft-versus-host disease (TA-GVHD) in immunocompromised individuals. Several reports have documented the presence of leukocytes in FFP,[143–146] which has led to questions regarding their clinical relevance as well as the need for further processing (e.g., leukoreduction, irradiation) of FFP to reduce the risks of leukocyte-associated complications. Leukocytes have also been implicated in cytokine generation, which is responsible for febrile nonhemolytic transfusion reactions and lung injury.

Willis and colleagues[145] demonstrated that the number of leukocytes in FFP spanned a 3-logarithm range, depending on the method of preparation, with 43% of units obtained by the hard-spin method and 45.7% of units produced by the second-spin method containing more than 5×10^6 leukocytes. These values are higher than the American Association of Blood Banks cutoff standard ($<5 \times 10^6$ per red blood cell unit)[147] and far above the European cutoff standard ($< 1 \times 10^6$ per red blood cell unit)[148] for residual donor leukocytes in the final leukoreduced product. It had been assumed that the freezing process renders FFP practically devoid of viable leukocytes.[149] Wieding[143] and Bernvil[144] and their associates demonstrated that viable lymphocytes may be present, raising concern about possible adverse immunomodulation (e.g, TA-GVHD) in certain individuals at risk and pointing out the potential benefit of using irradiated FFP. Other investigators, using propidium iodide (PI) and fluorescein-conjugated antibodies to determine viability, have shown that the majority of leucocytes in FFP are PI-positive (dead) cells.[146] Nevertheless, a small but consistent population of PI-negative (live) cells was detected, including viable $CD3^+$ T cells. Both dead and live cells expressed HLA class I antigens. Approximately 38% of these cells expressed HLA class II antigens. These investigators concluded that transfusion of FFP is potentially alloimmunogenic owing to its residual leukocyte content and that leukocyte-reduction filters appear to be effective in suppressing the alloimmunogenicity of FFP. Although the viability of leukocytes may be important in the pathophysiologic mechanism of some adverse reactions, their destruction may release cytokines that are implicated in the pathophysiologic mechanism of febrile nonhemolytic reactions. A relation between exposure to allogenic plasma and the risk of postoperative pneumonia or wound infection or both was not detected in a retrospective study of patients undergoing coronary artery bypass surgery.[150]

FFP produced by certain methods may therefore contain enough leukocytes to be categorized as a cellular blood product and to justify the use of a leukoreduction filter. The use of prestorage leukodepletion filters decreases the overall leukocyte burden (viable and nonviable) in the blood component and decreases the concentration of cytokines and anaphylatoxins. Leukodepleted FFP may be indicated for certain individuals at risk for these complications, including immunosuppressed individuals and patients requiring massive transfusions.[121]

Infectious Potential

Although leukocytes have been shown to be present in FFP, transmission of cell-associated viruses including cytomegalovirus (CMV) and human lymphocytotropic viruses (HTLV-I and -II) has been associated with cellular blood components and not FFP, although some authorities remained concerned that transmission is possible. In addition to the use of donor questionnaires and serologic surrogate markers, the introduction of SD plasma, which efficiently inactivates lipid-encapsulated viruses including HBV, HCV, HGV, HTLV, and HIV, has eliminated a great majority of transfusion-transmitted pathogens.[151] Nonetheless, nonenveloped viruses, including parvovirus B19 and hepatitis A virus, still pose concerns regarding the safety of SD plasma,

especially in immunodeficient individuals, pregnant women, and patients with chronic hemolytic anemias. Although SD plasma is a pooled product and may contain parvovirus B19 and hepatitis A virus, it also contains neutralizing antibody to these viruses, which may modify the risk of infectivity or its clinical significance. Furthermore, SD plasma is screened for these viruses by polymerase chain reaction, and lots with high viral loads are eliminated.[152,153] Other methods to reduce or inactivate pathogens in FFP have been developed. These include the treatment of plasma with methylene blue and white light[152] and the treatment of blood products such as platelet concentrates and FFP with psoralen and ultraviolet light.[154] As described earlier, FFP may be quarantined until after the donor has given a subsequent blood donation, is retested, and found to be negative for markers of transfusion-transmissible infection. This may obviate window-period infections.[11]

Another potential for transmission of infectious agents stems from the possibility of newly emerging pathogens in the donor pool, the presence of prions, or contamination during processing with agents not susceptible to inactivation by the SD process.[12–16] In the United Kingdom, it is recommended that the FFP given to neonates and children should be obtained from an area free of bovine spongiform encephalopathy (BSE) and be subjected to pathogen-reduction procedures.[52] In patients for whom pathogen-reduced plasma is being considered, the risks of HAV and parvovirus B19 transmission and their clinical sequelae should be weighed against the likely benefits. Patients likely to receive multiple units of FFP, such as those with a congenital coagulopathy, should be vaccinated against hepatitis A and B.[52]

Chapter 20

Cryoprecipitate and Related Products

Leon L. Su • Lennart E. Lögdberg

Cryoprecipitate (cryoprecipitated antihemophilic factor, Cryo) is the common term for the cold-insoluble plasma proteins that precipitate in fresh frozen plasma (FFP) when it is thawed to between 1°C and 6°C and then centrifuged, collected, and refrozen. It is one of the four main blood components available in virtually every blood bank in the developed world, but paradoxically, it is likely the component most underutilized even in well-recognized clinical circumstances.

The main constituents of cryoprecipitate are the high-molecular-weight proteins fibrinogen, factor VIII, von Willebrand factor (vWF), factor XIII, and fibronectin. Initially developed in the mid-1960s by Judith Pool and colleagues,[1,2] cryoprecipitate revolutionized the treatment of hemophilia and von Willebrand disease (vWD), previously dependent on whole blood or fresh plasma. Cryoprecipitate, because of its concentrated factor VIII and factor VIII-vWF complex, could be pooled, and thus its transfusion could provide sufficient factor to prevent or treat serious bleeding with minimized risk of volume overload. In the decades after the introduction of cryoprecipitate, purified and recombinant factor concentrates were developed and eventually supplanted cryoprecipitate as the primary treatment for hemophilia and vWD in most cases.

Today, cryoprecipitate use has been redefined. It is used primarily to treat acquired fibrinogen deficiencies associated with active bleeding and either surgery or trauma with dilution from massive transfusion and fluid resuscitation. It also is used in congenital deficiency syndromes associated with bleeding or as prophylaxis against anticipated bleeding. Finally, cryoprecipitate is used as a source of fibrinogen, factor XIII, and fibronectin in the commercial production of tissue sealants as well as the institutional production of allogeneic and autologous fibrin glues. Whereas it is no longer routinely used as the primary treatment for hemophilia, vWD, and uremic coagulopathy, cryoprecipitate continues to have a role as second-line therapy in instances in which primary treatment is ineffective or not available.

PRODUCTION, PROCESSING, STORAGE, AND QUALITY CONTROL

The source and quality of plasma used to make cryoprecipitate is controlled by guidelines set forth by the Food and Drug Administration (FDA) as published in the Code of Federal Regulations (CFR).[3] Governing the quality of source plasma ensures that production of cryoprecipitate contains adequate amounts of biologically active product while minimizing contamination from infectious and cellular components. Current guidelines from the CFR allow source plasma to be obtained from whole-blood collection or plasmapheresis, although the vast majority of cryoprecipitate used for transfusion in the United States comes from whole-blood donors. Plasma donors are required to meet similar and additional eligibility requirements as whole-blood allogeneic donors. A sample of blood collected at the time of donation is tested for ABO phenotype and communicable infectious diseases. Pathogen-reduction techniques such as nanofiltration, solvent-detergent treatment, and methylene blue-photoactivation also may be used to treat source plasma to reduce further the risk of infectious disease transmission.

Preparation of plasma begins with separation of blood cells by centrifugation to create a cell-free product. If the collection is in CPD, CP2D, or CPDA-1, separated plasma must be frozen at a temperature less than or equal to −18°C within 8 hours of collection. For blood collected in ACD, separated plasma should be frozen within 6 hours of collection. Once frozen, cryoprecipitate can be made from FFP within 12 months of collection. The process resumes when FFP is thawed at 1°C to 6°C to allow formation of the cryoprecipitate. A final separation step using centrifugation or a plasma expressor removes the residual precipitate from the thawed plasma, where it is then placed in individual, sterile bags and resuspended in 10 to 15 mL (up to 20 mL in "wet cryo") of plasma.[4–8] After the extraction process, cryoprecipitate must be refrozen within 1 hour.

In addition to the traditional method of cryoprecipitation production outlined earlier, efforts to improve efficiency and quality control in component processing led to the development of a new automated device capable of generating cryoprecipitate from plasma. The CryoSeal FS system (Thermogenesis Corp. Rancho Cordova, Calif.), currently not for sale in the United States and pending FDA approval, is a compact, computerized device designed to produce fibrin sealant in the autologous preoperative setting.[9] Alternatively, the CryoSeal system is an automated device with tightly controlled temperature cycling capable of producing cryoprecipitate within 1 hour.[10,11] The fibrinogen and factor VIII content in cryoprecipitate prepared by the CryoSeal system is comparable to that with traditional production methods.[10,11] Advantages of the CryoSeal system over manual preparation include standardization and faster production of cryoprecipitate.

Current American Association of Blood Banks (AABB) Standards require cryoprecipitate to be stored at −18°C, transported in a frozen state, and used within 12 months of the original date of collection.[12] As a final measure to assure quality of cryoprecipitate, the CFR dictates that quality of antihemophilic factor and fibrinogen should be tested monthly on at least four representative containers of cryo-

precipitate.[3] With every quality-assurance testing, the AABB Standard states that unpooled components of cryoprecipitated antihemophilic factor should contain a minimum of 150 mg of fibrinogen and 80 IU of coagulation factor VIII.[13]

PREPARATION, DOSAGE, AND ADMINISTRATION

Preparation

Before its administration, cryoprecipitate is thawed in a water bath at 30°C to 37°C for approximately 10 to 15 minutes. Pooling of cryoprecipitate bags is often done after thawing and before administration, as most adult patients are treated with multiple units (see later) of cryoprecipitate at once. Alternatively, pooling of cryoprecipitate can be performed before it is frozen and appropriately labeled as "Cryoprecipitated antihemophilic factor, pooled." To maximize the activity of the coagulation proteins, once thawed, cryoprecipitate cannot be refrozen and should be kept at temperatures of 20°C to 24°C for no longer than 6 hours.[14] To ensure sterility of the product, cryoprecipitate must be transfused within 4 hours if it is pooled.[12]

Cryoprecipitate contains a negligible amount of red blood cells and only a small amount of the isohemagglutinins anti-A and/or anti-B. Therefore compatibility testing and Rh testing are not required before its use in adults. Nevertheless, it is common practice for most institutions to provide ABO-compatible cryoprecipitate when available. In neonatal recipients, cryoprecipitate should be ABO-compatible because of the smaller plasma volumes in infants. Approximately 20 to 30 minutes must be allowed for thawing and pooling of cryoprecipitate units before administration. Prepooled units can often be thawed and ready for administration in about 10 to 15 minutes.

Dosing: First-line Indications

The dose of cryoprecipitate is based on several factors including its intended use, the desired target level of the specific factor to be repleted, and the approximate size of the recipient. For hypofibrinogemia, cryoprecipitate has been demonstrated to be an excellent source of therapeutic fibrinogen.[15,16] As a general guideline, the dose of cryoprecipitate necessary to replete a fibrinogen deficit may be estimated by using an empiric dose of 1 U of cryoprecipitate per 5 to 10 kg body weight, or alternatively, it may be calculated by using the following formula:

$$\text{Desired fibrinogen increment (g/L)} = (0.25 \times \text{number of units of cryoprecipitate})/\text{Plasma volume (L)}$$

This formula assumes 250 mg of fibrinogen per unit of cryoprecipitate and can be modified to reflect the actual fibrinogen content of the unit, if known.

A dose of 1 unit of cryoprecipitate per 10 kg body weight can be expected to increase the fibrinogen concentration by approximately 50 mg/dL in the absence of heavy consumption or bleeding. The frequency and duration of administration is based on the underlying condition. In acquired hypofibrinogenemia (e.g., L-asparaginase therapy, disseminated intravascular coagulation), a daily prophylactic regimen may be suitable. In conditions associated with hypofibrinogenemia and active bleeding (e.g., massive transfusion with bleeding), and when the measured fibrinogen is less than 100 g/dL, an initial pool of 10 units is needed, and up to three pools may be given in rapid succession. In this circumstance, frequent monitoring and replacement are recommended.

In congenital hypofibrinogenemia, fibrinogen replacement with cryoprecipitate should be reserved for episodes of active bleeding. In the normal steady state, fibrinogen has a half-life of approximately 3 days.[17] Although active bleeding may alter fibrinogen kinetics, a dosing schedule of cryoprecipitate infusion every 3 days may be an appropriate starting point for patients with congenital hypofibrinogenemia.

Because factor XIII has a long half-life (9 days) and levels of less than 5% are hemostatic, the recommended replacement dose and the frequency of cryoprecipitate administration in congenital factor XIII deficiency are 1 U per 10 to 20 kg body weight every 2 to 3 weeks.

Dosing: Second-line Indications

Cryoprecipitate can be used as a second-line treatment for hemophilia A when factor concentrates are unavailable. Typical regimens begin with a loading dose to achieve the desired factor VIII level, followed by maintenance doses every 8 to 12 hours. Larger doses may be necessary in cases with factor VIII inhibitor and can be adequately assessed and adjusted by monitoring factor VIII levels after treatment. The following formulas can be used to calculate the number of units of cryoprecipitate needed to achieve a target factor VIII level[4]:

Take the desired increase in factor VIII (percentage) and divide by 100 to obtain the desired factor VIII increase in units per milliliter. Factor VIII increase (in units per milliliter) multiplied with plasma volume (in milliliters) equals units of factor VIII needed. Assuming that each cryoprecipitate bag has a minimum of 80 U of factor VIII, the number of factor VIII units needed per 80 U per bag equals the number of bags or units of cryoprecipitate needed.

The quantity, quality, and activity of vWF in cryoprecipitate are variable. Therefore for the treatment of vWD and uremic coagulopathy, the replacement dose of vWF is estimated. For vWD, the usual recommendation is daily infusions of 1 U of cryoprecipitate per 10 kg body weight. In addition to clinical monitoring, appropriate laboratory studies should be performed to help individualize dosing strength and frequency of administration. For uremic coagulopathy, a similar dose of 1 U of cryoprecipitate per 10 kg body weight can be given as a one-time dose, with subsequent doses dependent on clinical and laboratory follow-up.

Preparation of Fibrin Glue/Sealants

Cryoprecipitate also may be used as a source of fibrinogen that can be added to a thrombin to form a *fibrin glue* or *sealant.* Fibrin glues and sealants are used as surgical hemostatic and adhesive agents that reproduce the final stages of the coagulation cascade to form fibrin clots. Fibrin glues and sealants can be divided into three categories including "home-made" preparations, commercially prepared fibrin sealants, and autologous fibrin sealant systems. Home-made glues have varying formulations that exist in the literature, but generally contain the basic components of cryoprecipitate, thrombin, and calcium chloride ($CaCl_2$).[18,19] Depending on how much fibrin glue is needed, common starting mixtures use 50 to 90 mL of cryoprecipitate combined with an equal volume of sterile

solution containing 25,000 to 50,000 U of thrombin and 0.5 to 1 g of $CaCl_2$. Although home-made glues are effective as hemostatic and adhesive agents, they are not FDA approved for such applications. Furthermore, traditional home-made formulations that contain bovine thrombin have been associated with adverse effects; these include anaphylaxis to bovine proteins and the development of factor V inhibitors, leading to coagulopathy and increased morbidity and mortality.[20–22]

Commercially prepared fibrin sealants contain the same basic components as most home-made formulations, with a few differences. In the commercial production of fibrin sealants, fibrinogen is extracted from pooled human cryoprecipitate and combined with a fibrinolysis inhibitor solution. Separately, thrombin is prepared from pooled human plasma and is activated just before use by the addition of $CaCl_2$. By using a water bath (37°C), the fibrinogen concentrate/fibrinolytic inhibitor component is mixed with the thrombin/$CaCl_2$ solution to form a fibrin clot at the surgical surface. Whereas several commercially prepared fibrin sealants are available on the global market, only two are currently FDA approved and available for use in the United States. The first FDA-approved fibrin sealant, Tisseel (Baxter Healthcare, Deerfield, Ill.), was introduced in the United States in 1998, followed by a second-generation fibrin sealant, Crosseal (American Red Cross), in 2003. An important distinction between the commercially prepared fibrin solutions and the home-made fibrin glues is the viral inactivation/removal step of commercial fibrin solutions. The thrombin and fibrinogen components of Tisseel are freeze dried and heat treated as a means of viral inactivation.[23] Crosseal is produced by using a different viral-inactivation procedure in which the fibrinogen and thrombin components undergo solvent detergent treatment as well as pasteurization of the fibrinogen and nanofiltration of the thrombin.[24]

The last category of fibrin sealants is the autologous fibrin sealant systems. These fibrin solutions are automated devices that use autologous whole blood or plasma to create the protein components of the fibrin solution. The clear advantage of these systems is the elimination of infectious risk for human blood-borne diseases. Two of the fibrin-based systems, VivoStat[25] (Vivolution A/S) and AutoSeal (Harvest Technologies), produce a proprietary fibrin sealant within approximately 20 minutes by extracting fibrinogen and other sealant components directly from autologous whole blood. Another autologous fibrin-sealant system is the previously mentioned CryoSeal FS system that creates the two main components of a fibrin sealant, cryoprecipitate, and thrombin, from autologous blood within 1 hour.[9] All three systems are available in the global market but are currently not approved for use in the United States.

CRYOPRECIPITATE CONSTITUENTS AND THEIR STABILITY

Cryoprecipitate is a plasma-derived product that contains a higher concentration of fibrinogen as compared with FFP. Whereas AABB Standards indicate that cryoprecipitate must contain a minimum of 150 mg of fibrinogen, most cryoprecipitate products using current methods of extraction will contain higher amounts of fibrinogen near the order of 250 to 350 mg of fibrinogen per bag, representing a recovery rate of approximately 30% of the original fibrinogen content.[9,10,16] Cryoprecipitate also contains 80 to 120 U of factor VIII, with a higher rate of recovery near 50% of the original factor VIII content.[10] Additional components include 30 to 60 mg of fibronectin, and a variable percentage of the original plasma concentration of vWF (approximately 40% to 70%), and factor XIII (approximately 30%). Remaining components include small amounts of immunoglobulin G (IgG), IgM, and albumin.[26] Different processing factors including preservative solutions (e.g., CPDA-1, ACD), temperature, time of storage, rate of centrifugation, rate of freezing, and viral inactivation procedures (e.g., methylene blue plus light, solvent detergent) have all been shown to have varying effects on the overall fibrinogen, vWF, and factor VIII content, and thus should be evaluated if quality testing reveals below standard component levels in the final cryoprecipitate product.[27–33]

Interestingly, whereas expiration times set forth by AABB and FDA serve to ensure the quality and safety of cryoprecipitate components, several studies show that fibrinogen levels remain stable and adequate up to 24 hours after thaw at room temperature and in units kept up to 8 years in frozen storage.[14,34–36] In contrast, factor VIII levels appear less stable than fibrinogen over time, and whereas some studies show that it remains adequate up to 24 hours after thaw and in units stored frozen for up to 8 years, conflicting data indicate that the quality of factor VIII can be consistently verified only within the standard guidelines.[14,34–36] Decisions to extend the expiration of cryoprecipitate based on medical necessity, therefore, should take into consideration the intended use of the product, the duration of expiration, and the possible increased risk of infectious contamination.

PRIMARY AND SECONDARY INDICATIONS FOR CRYOPRECIPITATE USE

Because cryoprecipitate contains the highest concentration of fibrinogen, factor XIII, and vWF, it is most often used in the treatment of hemorrhagic disorders resulting from quantitative or qualitative deficits of these factors. As factor concentrates and recombinant factors have become more readily available and affordable, the use of cryoprecipitate has declined. Table 20–1 lists primary and secondary uses of cryoprecipitate in addition to common misuses and underutilization of cryoprecipitate.

Quantitative and Qualitative Fibrinogen Deficiency

The common coagulation pathway culminates in the formation of the fibrin clot through the action of thrombin on fibrinogen. Thus congenital abnormalities in fibrinogen synthesis, either hypofibrinogenemia/afibrinogenemia or dysfibrinogenemia, may result in spontaneous or posttraumatic hemorrhage of variable degree. Various clinical entities including hepatocellular disease, disseminated intravascular coagulopathy, and L-asparaginase therapy may be associated with clinically significant hypofibrinogenemia or dysfibrinogenemia. In general, fibrinogen levels greater than 100 mg/dL are considered to be adequate for hemostasis whereas fibrinogen levels below 100 mg/dL frequently are associated with severe bleeding.[37] Although fibrinogen levels lower than 100 mg/dL result in the prolongation of the prothrombin and activated partial thromboplastin time, correction of the fibrinogen deficit is typically required only during episodes of active bleeding or before surgical procedures.[38–40]

Table 20–1 **Primary and Secondary Clinical Indications, Common Misuses, and Underutilization of Cryoprecipitate**

Primary
Acquired/congenital hypofibrinogenemia[16,38–39,43–44,47]
Massive transfusion with bleeding[48–51]
Component for tissue sealants or fibrin glues[23–24,72–92]
Factor XIII deficiency[60–65]
Reversal of thrombolytic therapy[93,97]
Secondary
Hemophilia A[4,94]
von Willebrand disease[34,52–59]
Uremic coagulopathy[66–71]
Common Misuses[97,98]
Fibrinogen replacement with normal fibrinogen levels and no evidence of increased dysfunction or consumption
Reversal of warfarin therapy
Treatment of impaired surgical hemostasis in the absence of hypofibrinogenemia
Treatment of hepatic coagulopathy with multiple factor deficiencies
Common Underutilization[48–51]
Massive transfusion with bleeding

In a review, Humphries[41] reported that the most common use of cryoprecipitate as fibrinogen replacement is in acquired fibrinogen deficiency. Dose and frequency of administration depend on the rate of consumption or destruction of fibrinogen, and this can be assessed by monitoring the fibrinogen level. In certain coagulopathies, repletion of other coagulation proteins in addition to fibrinogen may necessitate the use of FFP.[16,42–47]

Massive Transfusion

The coagulopathy associated with massive transfusion in bleeding is often multifactorial. However, the primary cause is usually coagulation factor deficiencies from dilution and increased factor consumption, as in disseminated intravascular coagulation or normal coagulation.[48] Situations of major blood loss with massive transfusion often lead to an initial decrease in fibrinogen levels below 100 mg/dL after loss of 1.5 blood volumes followed by a decrease to less than 25% activity of labile coagulation factors after loss of two blood volumes.[49,50] In some cases, rapid consumption and dilution of fibrinogen is associated with massive transfusion and bleeding, FFP dosing without additional cryoprecipitate may not be sufficient to maintain hemostatic fibrinogen levels. Although FFP does contain fibrinogen, the amount provided this way may be insufficient to maintain adequate levels during massive transfusion and bleeding, in turn leading to delayed correction and excessive volumes.[51] As a result, use of cryoprecipitate should always be considered in massive transfusion with bleeding and should be given early in the course along with FFP.

von Willebrand Disease

The complex adhesive glycoprotein vWF is synthesized by megakaryocytes and endothelial cells and circulates in plasma as multimers of various molecular weights (500 to 10,000 kDa). vWF has two important hemostatic functions: (1) it mediates platelet adhesion to the subendothelium through its interaction with platelet glycoprotein Ib, and (2) it stabilizes factor VIII by complexing with it in circulation.[52,53] Therefore, both quantitative and qualitative abnormalities in vWF can result in increased bleeding tendency. Desmopressin acetate [1-deamino (8-D-arginine) vasopressin] (DDAVP) enhances the release of vWF from the endothelial cells and augments platelet activity. DDAVP is considered effective therapy in most types of vWD. In approximately 10% to 20% of patients with vWD, however, DDAVP is either ineffective (types 1 and 3) or contraindicated (types 2B and 2N), or the development of tachyphylaxis prevents its prolonged use. In these circumstances, cryoprecipitate can provide adequate replacement of both vWF and factor VIII:C to shorten the bleeding time and to control clinical bleeding.[54–57] In the past 20 years, lyophilized and pasteurized plasma concentrates (e.g., intermediate-purity and high-purity plasma-derived factor VIII concentrates) rich in high-molecular-weight vWF and factor VIII, have been developed and have largely replaced cryoprecipitate in the treatment of vWD.[58,59]

Factor XIII Deficiency

Through the dual action of thrombin, fibrinogen is converted into fibrin, and factor XIII is activated; this process facilitates the cross-linking of polymerized fibrin and α_2-antiplasmin to fibrin clots. In the neonatal period, deficiency of this hemostatic function (factor XIII deficiency) manifests as protracted umbilical stump bleeding, whereas later in life, postsurgical bleeding and delayed or abnormal (keloid) wound healing may be observed. Factor XIII also has been linked to the development of implantation tissue during pregnancy, and its deficiency is believed to be the cause of repeated miscarriages.[60] In these cases of factor XIII deficiency, prophylactic replacement therapy with plasma-derived factor XIII concentrates such as Fibrogammin P[61,62] (available in certain countries but currently not licensed in the United States) or cryoprecipitate is feasible.[63–65]

Uremic Coagulopathy

Many patients with uremia have evidence of abnormal primary hemostasis, as documented by a prolonged bleeding time and decreased platelet aggregation, findings suggesting an abnormal interaction between platelets and vascular endothelium.[66,67] Because vWF promotes normal interaction between platelets and subendothelium, the use of cryoprecipitate in uremic bleeding has been reported in

a few small studies and case reports.[68–70] Janson and associates[68] described a significant reduction in bleeding time with improvement in uremic bleeding diathesis in a group of six patients. The beneficial effect of cryoprecipitate on uremic bleeding is transient and is observed in only up to 50% of patients.[71]

Fibrin Glue or Sealant

Fibrin glues and sealants are commonly used today to enhance local surgical hemostasis and to provide effective tissue adherence. The elastic property, tensile strength, and tissue adhesiveness of plasma fibrin glue or sealant has made it an important adjunct in microsurgical technique. As previously mentioned, many variations of fibrin glues/sealants are available, including home-made formulations, commercially prepared products, and autologous sealant devices, yet only two commercially prepared fibrin sealants are approved for specific use in the United States. Tisseel has been approved for use as an adjunct in conventional surgical hemostasis, cardiopulmonary bypass surgery, colostomy closure, and splenic injury repair.[23] Crosseal has been approved for use in hepatic surgery.[24,72,73] Although the efficacy of the two sealants have not been fully addressed in the literature, the composition and related adverse effects have been compared (Table 20–2). Tisseel incorporates a bovine aprotinin as the antifibrinolytic agent as opposed to Crosseal, which uses Tranexamic acid (a human-derived product). The advantage of using a bovine-free fibrin sealant such as Crosseal is that it does not carry the increased risk of anaphylactic reaction to bovine proteins[74] or the theoretic risk of bovine spongiform encephalopathy (BSE) transmission seen with Tisseel. One disadvantage of Crosseal is that there is an absolute contraindication to its use in procedures in which contact exists with the cerebrospinal fluid (CSF) or dura mater. Crosseal used in neurosurgical procedures on rabbits at doses equivalent to clinical use in patients demonstrated severe neurologic symptoms and death in the rabbits.[24]

A wide variety of investigational uses for fibrin glue and sealants are documented in the literature.[75–78] Although the approved uses of commercial sealants are limited, experimental or off-label uses of various fibrin tissue adhesives or sealants are numerous and are still expanding. Fibrin sealants have been used to achieve hemostatic control in patients with preexisting coagulopathy.[79] In cosmetic surgery, tissue fibrin adhesives have been used in lieu of sutures to reduce scar formation and in aiding skin-graft fixation in burn patients.[80–83] In various microsurgical techniques, fibrin sealants have been used to attain a fluid or air barrier, to maintain tissue adhesiveness, and as an adjunct in bone and cartilage repair.[84–89] As an extemporaneous fibrin glue, infusion of cryoprecipitate with thrombin into the renal pelvis facilitated the removal of small renal stones.[90] Applications of fibrin glues and sealants have also been investigated in repairing punctured fetal membranes as a potential treatment for premature rupture of membranes.[91] Similar to the concept of fibrin glue and sealants is the promising use of cryoprecipitate and platelets to form an "amniopatch" in the treatment of iatrogenic previable premature rupture of membranes.[92]

Other Uses

As a minimal-volume fibrinogen source, cryoprecipitate has been used to decrease bleeding during orthotopic liver transplantation and is indicated for reversal of thrombolytic therapy associated with bleeding.[93] In developing countries where factor concentrates are unavailable, cryoprecipitate can serve a primary role in the treatment of hemophilia A, if available.[94] As a source of fibronectin, cryoprecipitate was once believed to have potential in treating critically ill patients with organ failure and sepsis; however, it was proven not to have any such clinical benefit in several controlled studies.[95] In contrast, in a small, controlled study, Steinbaum and Cucinell[96] demonstrated a beneficial effect of cryoprecipitate containing fibronectin on wound healing. Further controlled

Table 20–2 **Comparison of FDA-Approved Commercially Prepared Fibrin Sealants: Tisseel and Crosseal[23,24,74]**

Tisseel	Crosseal
Approved Indications	
As adjunct to hemostasis in cardiopulmonary bypass surgery As a hemostatic agent in fully heparinized patients undergoing cardiopulmonary bypass surgery As adjunct in the closure of colostomies In the control of bleeding associated with splenic injury	As adjunct to hemostasis in liver surgery
Antifibrinolytic Agent	
Bovine aprotinin	Tranexamic acid
Contraindications	
Patients with a known hypersensitivity to bovine proteins or reactions to human blood products Injection into circulation or tissues Massive and brisk arterial bleed	Patients with known anaphylactic or severe systemic reactions to human blood products Surgical procedures in which contact with cerebrospinal fluid or dura mater could occur Injection into circulation or tissues Massive and brisk arterial bleeding
Potential Adverse Reactions	
Severe allergic/anaphylactoid reactions Thromboembolic events (if injected into circulation or tissue) Transmission of infectious agents (e.g., viruses)	Severe allergic/anaphylactoid reactions Transmission of infectious agents (e.g., viruses)

studies have yet to prove or disprove the use of fibronectin on wound healing, and its use in this area remains unclear.

COMMON MISUSES AND UNDERUTILIZATION OF CRYOPRECIPITATE

Audits of the use of cryoprecipitate have been reported in the literature and demonstrate that still considerable misuse of cryoprecipitate occurs in the clinical setting. Recent studies show patterns of inappropriate use involving up to 24% to 62% of all cryoprecipitate orders.[97,98] Commonly encountered misuses include fibrinogen replacement in patients with normal fibrinogen levels or who do not have current laboratory results *and* no evidence of increased dysfunction or consumption, reversal of warfarin therapy, treatment of impaired surgical hemostasis in the absence of hypofibrinogemia, and the treatment of hepatic coagulopathy with multiple factor deficiencies.

In addition, underutilization of cryoprecipitate in the setting of massive transfusion with bleeding commonly occurs in the intraoperative setting. The inappropriately low use of cryoprecipitate, and in some cases FFP, in the massive transfusion setting may stem from a once-held notion that coagulation deficiency occurred late in massive transfusion and after the development of thrombocytopenia. This belief, although probably valid when whole blood was used predominantly in massive transfusion, no longer reflects current practice, because today's blood products are mostly packed red blood cells (pRBCs) with significantly less plasma volumes.[48,50] As a result, coagulation deficiencies appear very early on in massive transfusion, with fibrinogen being one of the first coagulation proteins to fall below hemostatic levels.[49,50] Recent observations in the clinical setting suggest that during massive transfusion with bleeding, fibrinogen levels below 100 mg/dL may still persist despite repletion with pRBCs, FFP, and platelets, resulting in a persistent coagulopathy. Recognition of the rapid consumption and dilution of fibrinogen in the setting of massive transfusion and bleeding underscores the importance of frequent monitoring of fibrinogen levels and vigilant use of cryoprecipitate with other blood products to maintain hemostasis.

The incidence and pattern of inappropriate and insufficient use of cryoprecipitate signify an alarming misunderstanding of the use of cryoprecipitate among some clinicians and suggest the need for further education with respect to acceptable applications of this blood component.

POTENTIAL ADVERSE REACTIONS

Cryoprecipitate administration may be associated with nonspecific side effects related to its protein, cytokine, and isohemagglutinin content. Adverse reactions include fever, chills, and allergic reactions of variable severity. In situations in which large volumes of ABO-incompatible cryoprecipitate are given, adult recipients may develop a positive direct antiglobulin test (DAT), and in rare circumstances, hemolytic anemia.[4,99] Untoward effects of tissue fibrin adhesives such as home-made fibrin glues have been related to the source of thrombin, especially of bovine origin. These include the development of allergic-type reactions, some as severe as anaphylaxis, and factor V antibodies, which may lead to abnormal prothrombin times and postsurgical bleeding.[20–22]

SUMMARY

Cryoprecipitate is given primarily to treat acquired and congenital hypofibrinogenemia and is used in the production of fibrin glues and commercial sealants. Less frequently, it may be used to treat factor XIII deficiency and to reverse thrombolytic therapy. Cryoprecipitate may also be used as secondary treatment for hemophilia, vWD, and uremic coagulopathy or as initial treatment in situations in which specific factor concentrates or DDAVP are unavailable. Underutilization of cryoprecipitate in clinically appropriate circumstances and inappropriate use continue to occur at a high rate, according to institutional audits. This pattern of use underscores the need for continued education of ordering physicians on the appropriate use of cryoprecipitate.

Chapter 21

Albumin

Elizabeth E. Culler • Lennart E. Lögdberg

INTRODUCTION

Over the past 70 years, significant progress has been made in the isolation and purification of human plasma proteins for use as therapeutic products. This chapter focuses on albumin, the first such protein to be made commercially available through large-scale purification. The majority of this chapter will focus on the product Albumin (Human), a sterile solution of purified human plasma albumin, now dominating the therapeutic albumin market.[1] Less commonly used is Plasma Protein Fraction (Human), which is a sterile solution of albumin and globulin derived from human plasma.[1]

The development of a method to purify albumin was begun in 1940. By the end of 1941, human serum albumin (HSA) was put into clinical use on the battlefield.[2] The administration of human serum albumin proved so effective in the treatment of shock that the demand by the military resulted in the production of over 500,000 units in the United States by the end of World War II in 1945.[3]

In the decades following the war, albumin continued to be used in the treatment of shock but was also used experimentally in the treatment of various other conditions, such as malnutrition or hypoalbuminemia. Owing to the use of albumin for an expanding number of conditions and because of its significant cost, guidelines for albumin usage were established by the Division of Blood Diseases and Resources, National Heart and Lung Institute, National Institutes of Health, in 1975.[4] Since that time, further studies have prompted even more conservative albumin usage guidelines, such as those established by the University HealthSystem Consortium (UHC) in 2000.[5] Auditing of albumin transfusion practices, based on current guidelines, indicates substantial inappropriate use of this product.[6,7]

This chapter provides an overview of albumin products and begins by discussing plasma donation, the plasma industry, infectious disease testing, manufacturing methods, and regulatory aspects of albumin product production. This is followed by a review of the current guidelines for the therapeutic use of Albumin (Human), which is hereafter referred to as albumin. Finally, the adverse effect profile for the product will be summarized, including the risk of infectious disease transmission.

ALBUMIN, THE PROTEIN

Albumin is the quantitatively dominant plasma protein. A 66-kDa, water-soluble protein, it is synthesized in the liver at a rate of about 15 g/day and has a half-life of around 25 days.[8] In a healthy person with normal nutrition, albumin synthesis and catabolism are regulated by the colloid osmotic pressure.[9] An average 70-kg man contains about 320 g of albumin,[8] of which 35% to 40% is localized to the intravascular space, where it contributes about 80% of the colloidal osmotic pressure of plasma. Accordingly, albumin is important for physiologic maintenance and regulation of plasma volume.

In addition, albumin has a high negative charge[10] and a thiol group on the surface of the molecule that enables albumin to function effectively as a ligand binder, a radical scavenger, and a versatile transport protein.[11] Thus, albumin also serves as a major carrier for hormones, medications, enzymes, fatty acids, cholesterol, and many other substances.[9]

PLASMA DONATION AND COLLECTION

Albumin is derived from plasma collected either by whole blood donation (Recovered Plasma) or by apheresis (Source Plasma).[1] The following subsections discuss plasma collection and its regulation, plasma pooling, donor suitability, and prefractionation infectious disease testing. Refer to Chapter 12 for further information on these subjects and on the preparation and storage of Recovered Plasma and Source Plasma.

Regulation of Plasma Collection

The World Health Organization (WHO) has established guidelines for the collection and production of human plasma for fractionation.[12] In addition, regional or national regulatory authorities such as the U.S. Food and Drug Administration (FDA) and the Council of Europe are responsible for the establishment and enforcement of regulations pertaining to the safety and quality of the products in their respective areas.[13] The FDA inspects facilities that it licenses for plasma fractionation every 2 years. There are 26 facilities worldwide that are licensed by the FDA to produce plasma fractions for use in the United States.[14] In addition, almost all of the approximately 450 source plasma collection facilities in the world belong to the Plasma Protein Therapeutics Association (PPTA). The PPTA offers an International Quality Plasma Program (IQPP) certification requiring that facilities meet voluntary standards established by the PPTA. Approximately 90% of source plasma collection facilities around the world have qualified for IQPP certification. Source plasma facilities currently account for approximately 12 million liters of plasma production annually.[13]

Plasma Pooling

A donation of plasma by apheresis contains approximately 450 to 880 mL of plasma, while a donation of Recovered Plasma contains only around 100 to 260 mL of plasma.[12] Thus, albumin derived from pools of Source Plasma requires contributions from fewer donors than albumin derived from pools of Recovered Plasma. Because about 1 liter of plasma must be processed to produce 20 to 25 grams of albumin,[15] plasma from tens of thousands of donors must be pooled to make the production process efficient.

Donor Suitability

Pooling of the large number of plasma donations required to manufacture albumin allows a single infected donor unit the potential to transmit disease to a large number of final product recipients. Therefore, steps are added throughout the manufacturing process to limit infectious disease transmission. The initial step is to select appropriate donors by reviewing the donor's medical history and by conducting a medical examination. Although the WHO guidelines encourage the use of plasma from voluntary, nonremunerated donors,[12] many plasma collection facilities provide $15 to $25 per donation. To decrease the risk of infectious disease transmission, donors of Source Plasma must present themselves twice within a 6-month period to be considered acceptable by voluntary PPTA standards.[13] An "applicant donor" is an individual who comes in to donate and who has not qualified as a donor in the previous 6 months. Until the applicant donor screens negative for viral markers and passes the medical history screen on two separate occasions within a 6-month period, the initial donation is quarantined. When the donor successfully passes all tests twice within the 6-month period, the donor is considered "qualified" and the donations are used in manufacturing pools. When more than 6 months pass between donations, individuals are reclassified as "applicant donors" and must become qualified again. After donation, Source Plasma must be held for at least 60 days prior to pooling to allow time for investigation of any postdonation information that might become available.[13]

Infectious Disease Testing

After donors at low risk for infectious disease transmission have been selected, the plasma donations are screened using approved tests for hepatitis B surface antigen (HBsAg), anti–human immunodeficiency virus (HIV), and anti–hepatitis C virus (HCV).[12] The PPTA voluntary standards also require that nucleic acid testing (NAT) be performed for HIV, hepatitis B virus (HBV), HCV, and parvovirus B19. Manufacturing pools of plasma must contain less than 10^5 IU of parvovirus B19 DNA per milliliter according to PPTA standards.[13] Testing for HTLV-1 and HTLV-2 is not required because these are cell-associated viruses.[12]

The risk of infectious disease transmission is further reduced by the cold ethanol processing method and by filtration steps that eliminate microbes with diameters larger than 0.2 µm.[12] This is discussed below in the section on Commercial Albumin Preparations, Quality Specifications, and Formulations and the section on Infectious Potential.

MANUFACTURE OF ALBUMIN PRODUCTS

Development of a Technique for Plasma Fractionation

The development of a process for the isolation and purification of plasma components was driven by the need to provide blood products for casualties of World War II. In 1940, a meeting was held in Washington, D.C., to discuss the large number of blood products requested by the U.S. armed forces. Because of the limited supply, Dr. Edwin J. Cohn at the Harvard Medical School was asked to determine whether animal plasma could be used for human treatment.[16] Cohn developed a plasma fractionation technique (cold ethanol fractionation; see below) that he used to separate and characterize plasma components.[17]

Albumin, responsible for 80% of the colloid osmotic pressure of plasma, was the most suitable component for volume replacement.[18] Because bovine albumin was found to cause serum sickness in human recipients, the focus instead became the development of a human albumin preparation. Thus, treatment with a 25% human albumin solution was found to restore blood volume in volunteers made hypovolemic by removal of a measured volume of blood by venesection.[16] Further studies were cut short when the total albumin supply was needed at Pearl Harbor to treat burn victims.[16] The military experience with the product's clinical efficacy, ease of transport, and stability at a wide temperature range prompted initiation of mass production of albumin.[2] The 25% albumin solution used by the military contained sodium at a concentration of 300 mEq/L to maintain product stability. After the introduction of new stabilizers, the sodium content of albumin was reduced and the new product became known as "salt-poor albumin," a term still occasionally used within the medical community.[15] Currently the FDA requires that all albumin preparations contain 130 to 160 mEq/L of sodium.[1]

Producing plasma products during World War II was challenging. Of more than 12.5 million blood donations delivered to plasma processing facilities during this period, more than 204,800, or 1.6%, were ultimately rejected.[19] The biggest losses were due to bacterial contamination (>125,700 or 0.99% of the donations) or to breakage of the glass bottles used for plasma storage (>18,700 or 0.14% of the donations).[19] An investigation revealed that the main causes of bacterial contamination were the use of multiple technicians in the preparation process, break-in technique, nonsterile processing conditions, and, in some cases, collection facilities exceeding their capacity at the expense of quality. After these issues had been addressed, the rate of bacterial contamination was reduced.

Commercial Albumin Preparations, Quality Specifications, and Formulations

Because the implementation of new technology in albumin manufacturing requires a substantial capital investment and because the cold ethanol fractionation technique (see below) has a proven safety record, U.S. suppliers continue to use methods based on Cohn fractionation for albumin concentration and purification. In Europe, by comparison, some manufacturers have either incorporated chromatography into their production methods or switched to processes based exclusively on chromatographic purification methods.[20] The

addition of chromatography to plasma processing has significantly increased the yield (80% to 85% vs 60% to 70%) and purity (>98% vs 95%) of albumin products when compared to cold ethanol fractionation.[10] In addition, chromatography has allowed significant reductions in the concentration of unwanted elements such as endotoxin, aluminum, and trace proteins.[10] It is uncertain whether these alternative purification schemes will be incorporated into commercial albumin production in the United States.

Cold Ethanol Fractionation

Albumin purification using Cohn fractionation begins with frozen plasma, which is thawed at a low temperature, permitting the removal of cryoprecipitate. The product then undergoes cold ethanol plasma fractionation, which relies on the manipulation of pH, ionic strength, temperature, protein concentration, and ethanol concentration to precipitate plasma fractions. The ethanol content is increased and the pH and temperature are decreased in a stepwise fashion with separation of fractions by centrifugation and filtration. Fibrinogen is precipitated in fraction I, immunoglobulins in fraction II + III, α_1-proteinase inhibitor, antithrombin III, and factor IX complex in fraction IV-1, and plasma protein fraction in fraction IV-4. Albumin, which has the highest solubility of the major proteins in plasma, precipitates in the final fraction (fraction V). The ethanol is then removed by ultracentrifugation or freeze-drying.[21]

After the albumin has been purified and within 24 hours of being placed in the final container, the product is heated to 60 ± 0.5°C for 10 to 11 hours.[1] This inactivates a variety of viruses, including HBV and HIV. Albumin does not denature under these conditions owing to the presence of 17 stabilizing disulphide bonds in its structure[18] and to the addition of stabilizing compounds (sodium caprylate or a combination of sodium acetyltryptophanate and sodium caprylate). All final containers of albumin are incubated at 20–35°C for at least 14 days after heat treatment. After the incubation period, each final container is examined for turbidity before it is released.[1] The label on the final product must state the sodium (range in mEq/L) and the protein concentration (4%, 5%, 20%, or 25%).[1] Table 21–1 summarizes the FDA regulations pertaining to the production of Albumin (Human) and Plasma Protein Fraction (Human) and also lists FDA-required testing on the final albumin products.

Toward Commercialization of Recombinant Albumin

Over the past couple of decades, efforts have been directed toward producing recombinant human albumin.[22,23] A recent phase I trial compared the safety, tolerability, and

Table 21–1 **FDA Requirements for Manufacturing of Therapeutic-Grade Albumin (Human) and Plasma Protein Fraction (Human)**

Characteristic	Albumin (Human)	Plasma Protein Fraction (Human)
Required Production Characteristics		
Source material	Recovered Plasma or Source Plasma	
Pasteurization	Heated within 24 hours of the filling of the final containers at 60 ± 0.5°C for 10–11 hours	
Incubation	Incubated in final containers at 20–35°C for at least 14 days	
Processing	The processing method should not affect the integrity of the product and should consistently produce a safe product	Components with an electrophoretic mobility similar to that of α globulin should account for ≤5% of the total protein when tested after the pasteurization step The product should contain <5% protein with a sedimentation coefficient greater than 7.0 S
Stabilizer	Either 0.08 ± 0.016 mmol sodium caprylate or 0.08 ± 0.016 mmol sodium acetyltryptophanate and 0.08 ± 0.016 mmol sodium caprylate per gram of protein	
Preservative	None	
Required Tests on Final Products		
Protein concentration	The protein concentration of the final solution may be 4.0 ± 0.25%, 5.0 ± 0.30%, 20.0 ± 1.2%, or 25.0 ± 1.5%	5.0 ± 0.30%
Protein composition	≥96% of the total protein in the final product must consist of albumin, as determined by a Center for Biologics Evaluation and Research (CBER)–approved method	The protein composition of the final product must consist of ≥83% albumin and ≤17% globulins; ≤1% of the total protein should be gammaglobulin, as determined by a CBER-approved method
pH	When the final product is diluted to a concentration of 1% protein with sodium chloride 0.15 mol/L, the pH must be	
	6.9 ± 0.5	7.0 ± 0.3
Sodium concentration	130 to 160 mEq/L	
Potassium concentration	≤2 mEq/L	
Heat stability	The final product is inspected visually after it is heated to 57°C for 50 hours It must be not be visually different from an unheated control sample taken from the same lot	

From Code of Federal Regulations. Title 21 CFR 640. Washington, D.C., U.S. Government Printing Office, 2005 (revised annually).

hemodynamic responses in volunteers receiving either recombinant human albumin or human serum albumin.[24] Thirty participants in the double-blind, randomized trial received intravenous doses of 10 g on day 1, 20 g on day 22, and 50 g on day 43 of either recombinant human albumin or human serum albumin. There were no significant differences in safety or tolerability between the two products. The serum albumin, colloid osmotic pressure, and hematocrit pre- and postinfusion were measured and were not significantly different between the groups receiving either recombinant human albumin or human serum albumin. Since recombinant human albumin is virus- and prion-free, there is incentive for manufacturers to continue the clinical development of this product.

DOSING AND ADMINISTRATION

Choosing a Product

Albumin solutions with protein concentrations of 5%, 20%, and 25% are currently available on the U.S. market. Because PPF solutions contain a greater proportion of proteins other than albumin, they are not often used. Thus, the focus of this section is on albumin solutions.

The infusion of 5% albumin solutions, which are isooncotic with human plasma, increases the plasma volume by the volume of albumin solution infused,[8] while the infusion of the hyperoncotic 25% albumin solutions causes the plasma volume to expand by 3.5 times the volume of albumin solution infused.[25] For treating pediatric patients or volume- or sodium-sensitive patients, the more concentrated 20% or 25% albumin solutions are more commonly used, whereas the 5% albumin solutions are especially useful for hypovolemic patients.[26] Dehydrated patients usually require additional fluids along with the 20% or 25% albumin solutions.[1]

If necessary, a 5% albumin solution can be prepared by diluting a 20% or 25% albumin solution with either normal saline or 5% dextrose. Sterile water should not be used to dilute albumin because the resulting hypotonic solution can cause hemolysis when infused. This has occurred in at least 10 patients with one reported death.[27] When large volumes of diluted albumin are required, normal saline is the diluent of choice, since the infusion of large volumes of albumin diluted with dextrose 5% can cause hyponatremia leading to cerebral edema.[28]

When choosing a product, clinicians must also consider the aluminum concentration. As mentioned in the section on Potential Adverse Effects, albumin products contain small amounts of aluminum, which can accumulate in premature infants or in patients with chronic renal failure.[10] Talecris Biotherapeutics produces low-aluminum formulations of 5%, 20%, and 25% human albumin, each of which has an aluminum content of less than 200 μg/L.[29–31]

Dose

According to the American Hospital Formulary Service (AHFS) Drug Information guide, a typical initial adult dose of albumin is 25 g, which can be repeated in 15 to 30 minutes depending on the patient's response. Up to 250 g of albumin may be infused in a 48-hour period.[26] However, because studies have used different end points to assess clinical improvement after the administration of albumin, no standard dose of albumin can be recommended to fit all clinical situations. When evaluating the appropriate dose of albumin to administer, study investigators have relied on parameters such as serum albumin level, urine output, pulse, blood pressure, hematocrit, and degree of venous and pulmonary congestion.[26]

Rate

There are no guidelines addressing the optimal infusion rate for albumin solutions. The infusion rate should be based on the patient's condition and is limited only by the capacity of the administration set when an albumin infusion is needed emergently. Because high rates of albumin infusion can cause circulatory overload and pulmonary edema, 5% albumin solutions are commonly started at a rate of 1 to 2 mL/min and are not usually infused at a faster rate than 4 mL/min, and 25% albumin solutions are not infused at rates faster than 1 mL/min.[26]

Administration

Albumin should be inspected for turbidity prior to administration. Although albumin does not have to be infused through a filter, some manufacturers either recommend or include a filter in administration sets to be used during albumin administration. Hospital policy also may require the use of a filter.[15] Administration must begin within 4 hours of entry into the container.[1]

Because blood group isohemagglutinins are removed from albumin products during preparation, albumin is given without regard to ABO type. The Code of Federal Regulations (CFR) does not address the measurement of isohemagglutinin titers in albumin products; however, the European Pharmacopoeia states that plasma products intended for intravenous use should have an isohemagglutinin titer of less than 1:64.[12]

CLINICAL CONSIDERATIONS

Hypoalbuminemia may result from the decreased production, altered distribution, increased metabolism, or excessive loss of albumin. Some causes of decreased albumin production are liver dysfunction, malnutrition, and malabsorption. Approximately 40 cases of congenital analbuminemia (defined as HSA < 1 g/L) have been reported in the literature; however, this disorder is usually associated with only mild signs and symptoms.[32] Hypoalbuminemia also may result from a redistribution of albumin to the extravascular space as a result of increased vascular permeability, as seen in inflammatory states. Thyrotoxicosis and pancreatitis are two conditions associated with increased albumin catabolism. Increased albumin loss occurs in patients with protein-losing gastroenteropathy and nephrotic syndrome.

Indication Guidelines for Albumin Usage

Although decreased albumin levels are present in many conditions, albumin infusion is not usually required to treat hypoalbuminemia. Rather, albumin infusions are used therapeutically for plasma expansion. Historically, this led to broad indications and widespread use of the product. Later studies showed albumin to be ineffective in many of these uses, leading to a still-ongoing evolution toward more

conservative indication guidelines such as the most recent UHC guidelines for the use of albumin (summarized and updated in Table 21–2), nonprotein colloid, and crystalloid solutions.[5] Reflecting the liberal guidelines of the past, a 2003 report that examined albumin prescribing patterns in 53 member institutions of the University HealthSystem Consortium found that albumin was inappropriately used in 57.8% of adult patients and 52.2% of pediatric patients. In the report, which collected data on 1649 adult and 23 pediatric patients receiving albumin, two of the most common inappropriate uses of albumin were for intradialytic blood pressure support (159 patients) and for serum albumin values of <2 g/dL (142 patients).[6] The consensus of the panelists involved in creating the 2000 UHC guidelines for albumin use was that the available evidence did not support the use of albumin in these situations. Table 21–3 provides a list of common misuses of therapeutic albumin infusions.

In the following sections, we discuss alternatives to the use of albumin for plasma expansion and then summarize some of the well-recognized clinical indications for albumin infusions, noting that such infusions are often a secondary treatment option.

Alternatives to Albumin for Plasma Expansion

The two major categories of products that may be used for plasma expansion are crystalloids (e.g., 0.9% sodium chloride, Ringer's lactate) and colloids, including protein (e.g., albumin) and nonprotein substances (e.g., dextrans, gelatins, and starches). Crystalloids have not demonstrated a definite clinical advantage over albumin, but are considerably cheaper and are therefore widely used as first-line treatment.[33] Although nonprotein colloids have been associated with side effects such as alterations in hemostatic laboratory results, pruritus, and, rarely, with severe head and back pain, they also are less expensive than albumin and are preferred by some.[34–39] In those clinical conditions in which plasma expansion through albumin or nonprotein colloids has demonstrated equivalent patient outcomes, the 2000 UHC guidelines recommend the use of the latter due to their lower cost. Neither crystalloids nor colloids can be substituted for red blood cells when oxygen-carrying capacity is needed or for platelets or plasma when coagulopathy exists.[5]

Clinical Usage of Albumin Infusions

Therapeutic Plasma Exchange

Albumin is commonly used as the replacement fluid in therapeutic plasma exchange (TPE) unless a condition exists that specifically requires factors present in fresh frozen plasma (FFP).[40] Albumin solutions have a lower probability of viral transmission and a decreased risk of citrate-induced hypocalcemia than FFP.[41] According to the Circular of Information, FFP should not be used when other volume expanders can safely and adequately replace blood volume.[42]

Although albumin is a frequently used replacement fluid in TPE, cryopoor plasma or FFP are the preferred replacement fluids in thrombotic thrombocytopenic purpura (TTP) and related disorders.[43] In TTP, a metalloprotease (ADAMTS-13) that usually cleaves von Willebrand factor (vWF) into multimers is rendered ineffective by antibody inhibitors or by mutations in the ADAMTS-13 gene.[44–48] This results in the accumulation of ultralarge von Willebrand factor multimers, which interact with platelets, causing aggregation.[45,47] Plasma exchange treats the disease by removing the metalloprotease inhibitor and the ultralarge von Willebrand factor multimers and by replacing functional ADAMTS-13 metalloprotease through FFP or cryopoor plasma. Cryopoor plasma contains fewer ultralarge von Willebrand factor multimers than FFP does and is, therefore, preferred by some.[43]

The use of FFP as the TPE replacement fluid may also be considered in patients undergoing treatment with angiotensin-converting enzyme (ACE) inhibitors. In such patients, plasma exchange with albumin is associated with atypical reactions such as flushing, hypotension, dyspnea, and bradycardia.[49]

Paracentesis

Ascites associated with cirrhosis follows elevated portal pressure that results from increased intrahepatic vascular resistance, leading to increased nitric oxide levels and systemic arterial vasodilatation.[50] In patients with ascites, the vasoconstrictor systems become activated in response and the kidney retains sodium, causing ascites and edema.[50] Approximately 10% of patients with ascites are refractory to first-line treatment, which consists of a sodium-restricted diet and high-dose diuretics.[51] These patients' treatment options include serial therapeutic paracenteses, transjugular intrahepatic portosystemic stent shunt (TIPS), peritoneovenous shunts, and liver transplantation.[51]

For cirrhotic patients with refractory ascites who require serial therapeutic paracenteses, controversy exists concerning whether volume expansion is useful and, if so, which expander is most effective. A study by Gines and colleagues found that paracentesis in cirrhotic patients with tense ascites without albumin infusion resulted in significant increases in blood urea nitrogen, plasma renin activity, and plasma aldosterone concentration, whereas patients who received postparacentesis albumin did not experience those changes.[52] There were no significant differences in mortality between the groups. On the other hand, it has been shown that a single paracentesis of 4 to 6 L may be performed as a short-term option without albumin infusion in patients with tense, diuretic-resistant ascites.[51,53] Thus, given the safety of paracentesis of smaller volumes, the guidelines released by the American Association for the Study of Liver Diseases (AASLD) in 1998 suggest that postparacentesis albumin infusion is unnecessary for removed volumes of less than 4 to 5 L but that an albumin infusion can be considered for larger volume paracenteses.[51]

Alternatives to serial paracentesis with albumin infusion have been studied, and none has clearly demonstrated a better patient outcome. Albumin infusion more effectively prevents hemodynamic deterioration than the infusion of other plasma expanders such as dextran 70 and polygeline after large-volume paracentesis.[54] Results are conflicting when comparing treatment of cirrhotic patients with ascites refractory to diuretic treatment, with either TIPS or large-volume paracenteses followed by albumin, using survival without transplantation as outcome.[55–57] Because no other treatment has demonstrated a superior patient outcome, the 1998 AASLD guideline advising that albumin infusion be considered for large-volume paracentesis still seems applicable.[51]

Cirrhosis and Spontaneous Bacterial Peritonitis

Albumin infusion may be beneficial for patients with cirrhosis and spontaneous bacterial peritonitis, as demonstrated in a study in which such patients received either antibiotics or antibiotics plus albumin infusion.[58] The latter group had less renal impairment and a lower mortality rate. This clinical benefit may due to the thiol-related antioxidant effect of albumin.[59]

Nephrotic Syndrome

The nephrotic syndrome is caused by increased permeability of the glomerular capillary basement membranes, resulting in a urine protein excretion rate of greater than 3.5 g/24 hr.[60] Nephrotic syndrome is associated with hypoalbuminemia, edema, renal dysfunction, and hyperlipidemia. The standard treatment consists of corticosteroid and cytotoxic therapies to treat the underlying disease and diuretic therapy with a sodium-restricted diet to reduce peripheral edema and improve quality of life. A few patients may become refractory to these treatments. In such patients, investigators have attempted to increase diuresis by administering albumin in combination with furosemide with some success.[61] In one

study in which patients with hypoalbuminemia received either furosemide alone, albumin alone, or a mixture of the two, the latter regimen led to modest increases in sodium and volume excretion.[62] In contrast, more recent studies in nephrotic patients with hypoalbuminemia found no benefit in combining albumin with furosemide.[63,64] In fact, several detrimental effects have been linked to combined furosemide-albumin treatment, including response delays, frequent relapse to primary immunosuppressive therapy,[65] hypertension, respiratory distress, and electrolyte abnormalities.[66]

Given the above limitations, combining 25% albumin with diuretic drugs is primarily indicated for patients with nephrotic syndrome refractory to standard diuretic therapy with a sodium-restricted diet. Accordingly, the University Hospital Consortium Guidelines for the Use of Albumin, No-Protein Colloid, and Crystalloid Solutions recommend the short-term use of albumin with diuretics only for such refractory patients with acute, severe peripheral, or pulmonary edema.[67]

Ovarian Hyperstimulation Syndrome

Ovarian hyperstimulation syndrome (OHSS) is a complication of ovulation induction that occurs after the additional administration of human menopausal gonadotrophin (hMG) but rarely after the use of clomiphene citrate alone.[68] The incidence of severe OHSS is estimated to occur in 0.5% to 5% of in vitro fertilization cycles.[69] OHSS is graded as mild, moderate, or severe; in the last case, it can be fatal.[70,71] The pathophysiology of the syndrome is not yet clearly defined, but it is thought that the ovaries secrete vasoactive substances when final follicular maturation occurs, causing increased capillary permeability.[72] This results in the movement of protein-rich fluid out of the intravascular space, and patients can have vomiting, diarrhea, large ovarian cysts, thromboembolism, ascites, hydrothorax, hemoconcentration, oliguria, and anasarca.

Although the panelists involved in making the 2000 UHC guidelines concluded that there was not enough information on the pathophysiology of OHSS to recommend the use of albumin to prevent it, a recent meta-analysis demonstrated that albumin administration was effective in the prevention of severe OHSS.[73] The meta-analysis of five randomized controlled trials compared the use of human albumin with placebo or no treatment on patient outcome. The albumin dose ranged from 10 to 50 g and was given at 2 hours before, 1 hour before, or just after oocyte retrieval. Albumin infusion was estimated to prevent one case of severe OHSS for every 18 women at risk.

As an alternative treatment to albumin infusion, some clinicians have attempted to prevent OHSS by withholding gonadotropins (so-called coasting). A retrospective study comparing intravenous albumin and coasting found that the latter was as effective as albumin in preventing OHSS in high-risk patients but that pregnancy rates were lower.[74] Although prophylactic albumin infusion has been shown to prevent severe OHSS, it is unknown whether therapeutic albumin infusion for women with an established diagnosis of severe OHSS is effective.

Resuscitation and Volume Expansion in Critically Ill Patients

In the past, albumin was given for volume expansion in critically ill patients because it was assumed to be more effective than crystalloids at increasing plasma volume while minimizing interstitial volume expansion. However, Fleck and colleagues demonstrated that the rate of albumin loss from the vasculature to the tissue spaces was markedly increased in critically ill patients, such as those with cachectic cancer or septic shock and those who had undergone cardiac surgery,[75] suggesting that albumin administration may not be beneficial in these patient populations. Albumin infusion may also have detrimental effects and can cause renal dysfunction, decreased sodium clearance, and increased free water clearance in patients with hypovolemic shock.[76] It has been suggested that albumin inhibits platelet aggregation and enhances antithrombin III activity.[77,78]

In the late 1990s, a meta-analysis of 30 randomized controlled trials compared the use of albumin versus crystalloids or no albumin and found that when albumin was used to treat patients with hypovolemia, burns, or hypoalbuminemia the risk of death was 6% higher than in patients not treated with albumin.[33] The results prompted the FDA to issue a letter to health care providers on August 19, 1998, urging discretion in the use of albumin in the critically ill population.[79] Subsequently, a review of 17 studies found no difference in the incidence of pulmonary edema, length of hospital stay, and mortality in adult patients receiving crystalloids compared to those receiving albumin.[80] A meta-analysis of 55 trials conducted by Wilkes and Navickis[81] also did not show a significant difference in the mortality rate when albumin was administered versus crystalloids, no albumin, or lower doses of albumin. The patient populations studied included high-risk neonates, burn patients, patients with ascites, patients with hypoalbuminemia, and trauma patients, among others. The more recent Saline versus Albumin Fluid Evaluation (SAFE) trial[82] supported the conclusion of the Choi review and the Wilkes and Navickis meta-analysis.[80,81] The SAFE-trial randomly assigned 6997 ICU patients to receive either 4% albumin or saline for fluid resuscitation and found no significant differences in outcome in the number of days of mechanical ventilation, number of days in the ICU, length of the hospital stay, or in mortality rate at 28 days. The study included subgroups of patients with trauma, severe sepsis, and acute respiratory distress syndrome (ARDS); however, the study had insufficient power to draw conclusions regarding albumin use in these populations.[82] These studies prompted the FDA's Blood Products Advisory Committee (BPAC) to release an information sheet on May 16, 2005, indicating that the SAFE study resolved previous safety concerns and urging further studies on the use of albumin in burn patients and in patients with traumatic brain injury and septic shock.[83] An updated meta-analysis from the Cochrane Injuries Group concludes that that there is no evidence that albumin reduces mortality to a greater extent than much less expensive and equally safe options such as crystalloids in the overall critically ill patient population.[84] Table 21–2 lists subsets of critically ill patients (e.g., burn patients, patients in hemorrhagic or nonhemorrhagic shock, patients in particular postoperative situations, etc.) who may benefit from albumin administration according to UHC guidelines. In these situations, albumin is typically used when other treatments are ineffective.

POTENTIAL ADVERSE REACTIONS

The incidence of adverse reactions to albumin infusions is approximately 1 in 6600 infusions, with only 1 in 30,000

infusions being life threatening.[39] Most adverse reactions to albumin are mild and are either allergic in nature or are related to albumin's function as a volume expander. Some of the mild reactions that can occur include nausea, vomiting, increased salivation, chills, and febrile reactions.[85] Owing to albumin's role in increasing colloidal osmotic pressure and intravascular volume, rapid infusion can result in circulatory overload, pulmonary edema, and decreases in hematocrit and hemoglobin. Albumin, with its high negative charge, binds calcium and can also cause complications related to hypocalcemia.[86] In addition, because albumin contains aluminum in trace amounts, large doses can cause aluminum to accumulate in patients with chronic renal failure and lead to hypercalcemia, vitamin D–refractory osteodystrophy, anemia, and severe progressive encephalopathy.[8]

PPF preparations can cause allergic reactions and reactions related to intravascular volume expansion as well. PPF differs from other albumin-containing solutions because it includes a larger percentage of proteins other than albumin. PPF has been associated with hypocoagulability, which could be due to the platelet factor-4 and β-thromboglobulin present in the preparations. Owing to a higher concentration of contaminating proteins such as PKA, PPF causes more hypotensive episodes than albumin does and has been associated with metabolic acidosis in patients with renal dysfunction.[21]

INFECTIOUS POTENTIAL

Because plasma derivatives are made from pooled plasma from thousands of donors, reduction of infectious disease transmission is an important issue in plasma processing. The process of cold ethanol fractionation significantly reduces the concentration of viruses in plasma fractions. The pasteurization process also limits the transmission of infectious agents by denaturing viral proteins and nucleic acids, inactivating the viruses.[87–90] When plasma is deliberately spiked with viruses, the manufacturing process for the production of 25% albumin results in a global viral reduction ($\log_{10}$) of ≥17.8 for HIV; ≥16.3 for bovine viral diarrhea virus (BVDV), which is a model virus for HCV; and ≥16.4 for pseudorabies virus (PRV), which is a model virus for HBV.[91] The process results in a global viral reduction ($\log_{10}$) of 14.9 for reovirus, which is a small, nonenveloped virus; 7.8 for hepatitis A virus (HAV); and 6.8 for porcine parvovirus (PPV), which is a model virus for parvovirus B19.[91] There has never been a report of HIV or hepatitis C transmission through albumin infusion. One hepatitis B outbreak was reported in relation to PPF infusion in 1976,[92] but it probably resulted from a lack of uniform heating of the bulk product during the pasteurization process. Since 1977, the FDA has required that the heating step take place after the product is placed in individual containers.[1] Since that time, there have been no other reports of hepatitis B transmission through albumin products. Since albumin is acellular, cell-associated viruses such as CMV and Epstein-Barr virus are eliminated from the final product.

Cold ethanol fractionation and pasteurization reduces but does not eliminate the risk of bacterial contamination of albumin products. An outbreak of *Pseudomonas* bacteremia occurred in seven patients who had received albumin from the same lot in 1973. When 190 albumin vials from the suspected lot were cultured, one vial grew *Pseudomonas cepacia*. A subsequent experiment showed that, in addition to *P. cepacia*, *Escherichia coli*, *Bacillus subtilis*, *Candida albicans*, and *Staphylococcus epidermidis* also are able to grow in 25% albumin. In the experiment, *P. cepacia* remained viable in sealed vials of albumin kept at room temperature for 17 months after inoculation.[93] Although albumin solutions can support the growth of many types of bacteria, bacterial contamination of albumin products is rarely reported in the literature.

CONCLUSION

The development of therapeutic albumin formulations was critical for soldiers in need of volume support during World War II. Over the decades following that war, albumin was used in a wide variety of settings despite the relative lack of published evidence supporting its use in those situations. This led to the establishment of guidelines in 1975 that recommended more conservative use of albumin.[4] Since that time, studies have compared albumin with alternative fluids for volume expansion. When crystalloid administration was compared with albumin use in several clinical situations, no significant difference was demonstrated in terms of patient outcome.[80–82] Thus, usage guidelines for albumin have become even more conservative. Since albumin is more expensive than crystalloids and is a plasma derivative with related risks, crystalloids currently serve as first-line therapy for plasma expansion in most cases. The exceptions are those clinical scenarios in which albumin has demonstrated a significant clinical benefit over crystalloids, including large-scale therapeutic plasma exchange. At present, albumin is a valuable second-line treatment in many patients with conditions refractory to other plasma expanders.

Chapter 22

IVIG and Derivatives

Elizabeth E. Culler • Lennart E. Lögdberg

INTRODUCTION

The immunoglobulins (Igs)[1] constitute a major class of structurally similar globular plasma proteins. Owing to their antibody activity they are the principal effector molecules of specific humoral immunity, but they also function as broad regulators of immune system activity. The elucidation of the biochemical structure of Ig proteins and their corresponding genes unraveled the molecular basis of antibody activity and diversity in the 1960s and 1970s.[2]

The diversity of Ig genes is known to be inherited in the germline, then magnified by recombination during embryonal development and expressed in each individual as a polyclonal B-lymphocyte repertoire.[2] Each B-lymphocyte clone carries its own unique cell surface Ig molecule and therefore a single antibody specificity. During an immune response, the provoking agent (antigen) interacts with and activates the B-cell clones that have a cell surface Ig containing a matching antibody combining site. Following activation, these B-cell clones differentiate into plasma cells, each of which mass-produces and releases soluble Ig molecules with the same or improved (by somatic mutation and further antigen-driven selection) antibody specificities as the parental B-cell clone.

The progress with respect to our molecular understanding of Ig has been paralleled, in the last few decades, by improved methods to select, produce, purify, and manufacture therapeutic Ig products. These methods include development of the hybridoma technology, allowing production of homogenous Ig molecules with predefined, single-antigen specificities (monoclonal antibodies [MABs]).[3] At present, there is a wide array of such products on the market, including both polyclonal and monoclonal preparations. The polyclonal products represent either attempts to capture representative sets of polyclonal Ig (mainly, intravenous immunoglobulin[IVIG]), or polyclonal Ig selected for particularly high titers of antibodies against a given antigen (hyperimmune globulin or hyper-Ig). Therapeutic MABs have mostly reached the market in the last decade.[4] Each MAB product has been selected to react with a specific pharmacologic target, usually a cell surface receptor or a soluble bioactive mediator.

Today, polyclonal Ig products have a wide range of therapeutic uses most falling within three broad clinical categories. IVIG is the main product for two of these: *replacement therapy* for patients with congenital or acquired deficiencies of humoral immunity (e.g., hypo- or agammaglobulinemia) and *immunomodulation*. Hyper-Ig preparations, by comparison, are therapies of choice for *transferring specific passive immunity*, particularly used in four situations: (1) prophylaxis or treatment of infectious diseases; (2) neutralization of toxins, venoms, or drug overdoses; (3) prevention of alloimmunization; and (4) selective immunosuppression.

At present, the FDA has approved the use of IVIG for six indications with nine products on the market.[5–13] However, because of its wide-ranging immunomodulatory effects, IVIG increasingly is being used off-label to treat a diverse assortment of diseases.[14,15] At present, the off-label use of IVIG exceeds the product's use for FDA-approved indications.[15] Similarly, a large number of hyper-Ig products are approved for their respective niche markets.

The development of therapeutic MABs represents a revolution in immunotherapy with all but 2 of the 17 marketed MAB products achieving FDA-approval in the last decade. Indications for these products include the treatment of organ allograft rejection, autoimmune or allergic diseases, and some types of malignant tumors. With over 400 additional MABs in clinical trials, Paul Ehrlich's now century-old dream of creating "magic bullets" for selective treatment of diseases is being realized.[16]

This chapter reviews the characteristics and clinical uses of the various Ig preparations that are FDA-approved for therapeutic administration in the United States.

DEVELOPMENT OF IMMUNOGLOBULINS FOR THERAPEUTIC USE: A SHORT HISTORY

Igs were first detected as antibody activity more than a century ago when, in 1890, Emil von Behring and Shibasabo Kitasato discovered that exposure of animals to diphtheria toxin induced them to produce soluble factors in plasma/serum that could transfer protection against diphtheria to "nonimmune" humans.[17] The factor responsible for this *passive immunity* was called "antitoxin." A decade later, Paul Ehrlich recognized that humans can also actively mount their own similar "antibody" responses specific to toxins or bacteria, providing the body with *active immunity* to the relevant pathogen.[16] He further suggested that such "magic bullets" might be involved in warding off tumors. Before the development of antibiotics and other antimicrobial drugs, passive serotherapy for infectious diseases became the first clinical use of Ig.

During World War II, cold ethanol fractionation was used to mass produce the protein fraction responsible for antibody activity (later shown to be polyclonal Ig).[18] As IV agents, however, these preparations caused chills, fever, and shock, later shown to be due to the presence of high-molecular-weight aggregates in the product.[19] Intramuscular (IM) administration of Ig using lower doses became the predominant mode of delivery and resulted in fewer side effects. In fact, this was the route used by Bruton when he successfully

treated a patient with congenital agammaglobulinemia,[20] thus demonstrating, for the first time, the efficacy of exogenous Ig to confer global passive immunity and prevent infection in patients broadly deficient in humoral immunity.

Despite the limited doses of Ig that could be administered IM, this injection route continued to be the primary method of Ig administration until 1981, when a new processing method limited aggregate formation in the Ig preparations. This enabled the safe IV administration of large Ig doses[19] and rapidly led to the approval of IVIG formulations that now dominate the market.

In addition to the expanded use of IVIG in the modern era, hyper-Ig formulations also have been developed for the treatment of specific infectious diseases.[21] Like IVIG, the hyperimmune Igs are polyclonal Igs purified via fractionation of large plasma pools. However, in the latter case the pools are derived either[1] from specifically immunized (vaccinated) donors or[2] by preselecting specific high-titer plasma donations before pooling.

The hybridoma technology to develop murine MABs was described in 1975[3] and quickly led to attempts to develop therapeutic products. However, the first generation of therapeutic MAB candidates largely failed in clinical trials because of their tendency to provoke human anti-mouse antibody (HAMA) responses in the patients.[4] After many years of efforts to overcome the technologic difficulties, researchers are now proficient in creating and developing "near human" or fully human MABs with antibody specificity directed against human target molecules. This has resulted in FDA approval for clinical use of many products of this kind in the last decade.

IMMUNOGLOBULINS: PHYSICOCHEMICAL AND BIOLOGICAL ASPECTS

Ig proteins, then, are the family of molecules that carry antibody activity.[2] These proteins are synthesized and secreted by plasma cells, originating from resting B lymphocytes activated by antigen during an initial immune response. The B lymphocytes are "clonally selected" for activation by the antigen because they synthesize and express a cell surface Ig molecule reacting with sufficient avidity with the same antigen. This cell surface Ig is, in essence, of the same specificity as the soluble Ig molecule that their clonally expanded activated offspring—the plasma cell—will mass-produce.

The basic structure of an Ig molecule consists of two identical heterodimers, each comprising a larger (heavy [H]) and a smaller (light [L]) polypeptide chain linked by interchain disulfide bonds. The two heterodimers are kept together by disulfide bridges between the two H chains. Each H and L chain, in turn, is composed of a variable (V) and a constant (C) region, organized in globular units called Ig domains [V_H,C_{H1}, C_{H2}, C_{H3}, (C_{H4}), V_L, and C_L], the two V regions (V_H and V_L) together forming an antigen-binding site. The contact residues of this binding site are largely encoded by the so-called hypervariable regions of the V genes, whereas the rest of these genes are thought of as "framework regions."

The basis for antibody diversity, that is, that the immune system is intrinsically capable of mounting tailor-made antibodies to the universe of foreign antigens, is a combination of[1] inherited germline diversity of both V_H- and V_L-gene-families,[2] so-called junctional diversity, which occurs when IgC- and IgV-region genes recombine during development of B lymphocytes from their progenitor cells,[3] combinatorial diversity due to cooperation of diverse V_H- and V_L-gene products in creating the antigen-binding site, and[4] somatic hypermutation of hypervariable region V-gene codons during B-lymphocyte activation, combined with reselection by antigen of those B-lymphocyte clones that possess higher affinity Ig receptors.

There are five linked, but distinct, H-chain C genes (α, δ, ε, γ, and μ) on human chromosome 14 that can recombine with members of the same, linked V_H-gene family if selected during lymphocyte development and plasma cell differentiation. Each H-chain constant region confers different physicochemical and biological properties to the resulting plasma Ig molecule, leading to five Ig classes (or *isotypes*): IgA, IgD, IgE, IgG, and IgM. IgG is the predominant isotype in plasma (75% of plasma Ig). IgG, of which 55% is found extravascularly, is second only to albumin among plasma proteins in quantity, with a concentration of about 10 g/L. The plasma half-life of IgG is about 3 weeks, and it is the only Ig class that crosses the placenta. The plasma IgG of a donor represents a mixture of IgG species from thousands of different plasma cell clones and their precursors actively produced during the last several months prior to donation.

Enzymatic cleavage of the double IgG heterodimer yields two Fab´ fragments (V_H,$C\gamma_{H1}$- V_L,C_L) or one $(Fab')_2$ fragment (depending on the enzyme used) and one Fc fragment ($C\gamma_{H2}$, $C\gamma_{H3}$-$C\gamma_{H2}$, $C\gamma_{H3}$). Each Fab´ fragment contains an *a*ntigen-*b*inding site (V_H,V_L), a complete L chain (V_L, C_L), and the first part of the H-chain constant region (C_{H1}). The *c*rystallizable Fc-fragment consists of a homodimer of the remaining parts of the H-chain constant regions, which make up the binding site for (1) cellular receptors (Fc receptors) on various cells, such as monocyte/macrophages and granulocytes, and (2) proteins of the complement cascade.

The other four Ig classes have physicochemical and biological properties that are distinct from those of IgG, including their own Fc receptors on a variety of immune system–related effector cells. Thus, they likely fulfill important and unique functions in host defense, such as during the initiation of primary immune responses (IgD and IgM are the predominant receptor molecules on naive B lymphocytes) or when mucosal immunity is needed and they serve as secretory molecules.

However, IgG molecules appear to function as the main humoral basis of long-lasting immunity. This critical role and their high prevalence have made them the predominant Ig molecules selected for therapeutic development thus far. The bulk of the clinical experience has been with polyclonal IgG, but the last few years have witnessed a rapidly expanding clinical database of patients treated with FDA-approved MABs.

POLYCLONAL IMMUNOGLOBULINS

The original therapeutic use of Ig was as a transfer vehicle of passive immunity against specific infectious disease agents through serotherapy.[16] The idea of using polyclonal Ig to transfer *global* passive immunity to individuals with broad humoral immunodeficiency was realized much later. Whereas the latter use is a direct replacement therapy that relies on the therapeutic product to transfer broad representative humoral immunocompetence, the former use can be seen as a version of agent-specific passive protection during

a vulnerable period, before otherwise immunocompetent individuals have mounted their own responses. In both cases, though, polyclonal Igs are used. In addition, in both cases, the therapeutic products are manufactured from plasma pools.

In the first case, the goal is to transfer specific antibodies against selected antigens using an Ig preparation with high titers against these antigens. This kind of Ig preparation is represented by the various commercialized *hyper-Ig products.* In conferring global passive immunity, by comparison, the goal is to create an Ig preparation with a representative spectrum of antibody titers reflecting average humoral immunocompetence. This kind of Ig preparation is represented by the *IVIG products* currently on the market.

Commercial Production

IVIG

IUIS/WHO GUIDELINES FOR IVIG PRODUCTION

FDA regulations regarding polyclonal Ig production were established for IM formulations only and have not been updated to cover IVIG products.[22] Unique specifications for IVIG production are determined for each manufacturer through negotiations prior to approval of the Biologics License Application.[15] Although each manufacturer produces IVIG using a different combination of steps, most manufacturers follow the general guidelines established for IVIG production by the IUIS/WHO (International Union of Immunological Societies/World Health Organization) in 1982[23]:

1. The *source* material should be plasma obtained from a pool of at least 1000 donors.
2. For *safety* purposes, the final products should be virtually free of prekallikrein activator, kinins, plasmin, accumulative preservatives, or potentially harmful contaminants. The IgA concentration and the level of IgG aggregates should be as low as possible.
3. To meet *quality control* guidelines, the products should contain at least 90% intact IgG. The IgG should maintain opsonin activity, complement binding, and other biological activities. The IgG subclasses should be present in similar proportions to those in normal pooled plasma. The antibody levels against at least two species of bacteria (or toxins) and two viruses (by neutralization) should be determined. There must be at least 0.1 IU of hepatitis B antibody per milliliter and a hepatitis A radioimmunoassay titer of at least 1:1000.
4. The manufacturer should *specify the contents* of the final product including the diluent and any other additive used. Any chemical modifications of the Ig made by the manufacturer should be described.

PLASMA COLLECTION FOR IVIG PRODUCTION

The process of plasma collection is regulated by the FDA.[22] Many plasma collection facilities belong to the Plasma Protein Therapeutics Association (PPTA), which offers an International Quality Plasma Program (IQPP) certification requiring that facilities meet voluntary standards established by the PPTA.[24] In addition, WHO has published guidelines pertaining to plasma collection.[25] Chapter 19 provides more detailed information on determining donor suitability for plasma collection, prefractionation infectious disease testing, and regulation of the plasma industry.

IVIG is derived from plasma collected either by whole blood donation (Recovered Plasma) or by apheresis (Source Plasma).[22] Plasma so obtained is pooled to serve as the starting material for IVIG production. Source plasma accounts for approximately 80% and plasma recovered from whole blood accounts for about 20% of the plasma used for the manufacture of IVIG.[15]

SIZE OF PLASMA POOLS

Although the IUIS/WHO regulations for IVIG set the minimum number of donors from which plasma should be obtained for immunoglobulin production at 1000,[23] currently there is not a similarly set maximum number of donors that can be pooled. The pool size is proprietary information and is unique to each manufacturer, but it is thought that plasma from several hundreds of thousands of donors are typically pooled to create IVIG products, leading to enhanced concerns about infectious disease transmission. In 1997, the Subcommittee on Human Resources of the House Committee on Government Reform and Oversight requested recommendations from the National Institute of Allergy and Infectious Diseases regarding the minimum donor pool size needed for safety and efficacy of immunoglobulin products.[26] An expert panel determined that there was not enough scientific data to set a minimum number of donors to ensure an effective product. Because of the proven safety record of the currently produced formulations and because limiting the donor size could limit the supply of the product, the panel decided not to recommend capping the donor size below that which is currently used.[26]

PROCESSING METHODS

In addition to differences in the source of plasma, manufacturers also differ in (1) the steps used to fractionate, purify, and stabilize Ig, (2) the methods used to inactivate and/or remove viruses from the preparations, and (3) the formulation of the final product.[27] This variation causes differences in composition between the brands of IVIG products, some of which can be clinically significant. Table 22–1 lists some of these differences in processing methods and final composition among marketed IVIG products.

In general, Igs are isolated from the plasma using modifications of the cold ethanol fractionation method (see Chapter 12). The product is further purified and the viral load is reduced by means of filtration steps (e.g., nanofiltration, ultrafiltration, depth filtration), chromatography, and precipitation. Viruses may be inactivated physically by heat (e.g., pasteurization) and chemical/enzymatic methods (e.g., incubation at low pH with or without enzymatic treatment, or treatment with methylene blue, psoralens, riboflavin, caprylate, or solvent detergents).[27]

Many of these steps not only limit viral transmission but also serve to reduce the concentration of IgG aggregates. Examples of such approaches are ion exchange chromatography, treatment with pepsin at a pH of 4, and use of polyethylene glycol (PEG) to precipitate aggregates. Simply maintaining the product at pH 4 during storage limits aggregate formation because IgG exists almost exclusively in a monomeric form at this pH.[28] The fraction of IgG aggregates in the product may also be limited by the addition of stabilizers such as sucrose, glucose, glycine, maltose, sorbitol, and albumin.[28]

Table 22–1 **Available IVIG* Preparations, Methods of Production, and Composition**

Product	Manufacturer	How Supplied	Method of Production	Additive	Osmolarity or Osmolality	pH	IgA Content
Carimune NF IV	ZLB Behring	Lyophilized, 1, 3, 6, or 12 g	Cold ethanol fractionation and depth filtration, pH4/pepsin, nanofiltration	1.67 g sucrose/g of protein, <20 mg sodium/g of protein	192–1074 mOsm/kg (depending on concentration and diluent used)	6.4–6.8	Trace
Flebogamma 5%	Grifols	Liquid, 10 mL (0.5 g), 50 mL (2.5 g), 100 mL (5.0 g), 200 mL (10.0 g)	Cold ethanol fractionation, polyethylene glycol precipitation, ion exchange chromatography, pasteurization at 60°C for 10 hours	50 mg/mL of D-sorbitol, <3.2 mEq sodium/L, ≤6 mg PEG/mL	240–350 mOsm/L	5.0–6.0	<0.05 mg/mL
Gammagard S/D	Baxter Healthcare	Lyophilized, 2.5 g, 5 g, 10 g	Cold ethanol fractionation, ultrafiltration, ion-exchange chromatography, solvent/detergent treatment	20 mg/mL of glucose, 22.5 mg/mL glycine, 3 mg/mL albumin, 8.5 mg sodium/mL, 2 mg PEG/mL	5% 636 mOsm/L, 10% 1250 mOsm/L	6.4–7.2	≤2.2 μg/mL
Gammagard liquid 10%	Baxter Healthcare	Liquid, 10 mL (1.0 g), 25 mL (2.5 g), 50 mL (5.0 g), 100 mL (10.0 g), 200 mL (20.0 g)	Cold ethanol fractionation, chromatography, solvent/detergent treatment, nanofiltration, low pH incubation	0.25 mol/L of glycine	240–300 mOsmol/kg	4.6–5.1	37 μg/mL
Gammar-P IV	ZLB Behring	Lyophilized, 1 g, 2.5 g, 5 g, 10 g	Cold ethanol fractionation, pasteurization at 60°C for 10 hours	50 mg/mL of sucrose, 3% albumin, 5 mg sodium/mL	5% 309 mOsm/L, 10% 600 mOsm/L	6.4–7.2	<25 μg/mL
Gamunex 10%	Talecris Biothera-peutics	Liquid, 10 mL (1.0 g), 25 mL (2.5 g), 50 mL (5.0 g), 100 mL (10.0 g), 200 mL (20.0 g)	Cold ethanol fractionation, caprylate precipitation/cloth filtration, caprylate incubation, depth filtration, column chromatography, low pH incubation	0.16–0.24 mol/L of glycine, trace sodium	258 mOsm/kg	4.0–4.5	0.046 mg/mL
Iveegam EN	Baxter Healthcare	Lyophilized, 0.5 g, 1 g, 2.5 g, 5 g	Cold ethanol fractionation, 12% alcohol precipitation, ion exchange chromatography, incubation with immobilized hydrolases, and PEG precipitation	50 mg/mL of glucose, 3 mg sodium/mL, <0.5 g PEG/dL	≥240 mOsm/L	6.4–7.2	Trace
Octagam	Octapharma USA	Liquid, 20 mL (1 g), 50 mL (2.5 g), 100 mL (5 g), 200 mL (10 g)	Cold ethanol fractionation, ultrafiltration, chromatography, S/D treatment, pH 4 treatment	100 mg/mL of maltose, ≤30 mmol sodium/L	310–380 mOsmol/kg	5.1–6.0	≤1 mg/mL
Polygam S/D	Baxter Healthcare	Lyophilized, 1 g, 3 g, 6 g, 12 g	Cold ethanol fractionation, ultrafiltration, ion-exchange chromatography, solvent/detergent treatment	1.67 g sucrose/g of protein, <20 mg sodium/g of protein	192–1074 mOsm/kg (depending on concentration and diluent used)	6.4–6.8	Trace

*IVIG should never be frozen.
Data from refs. 5 through 13.

Hyper-Ig

Hyper-Ig preparations are manufactured much in the same manner as IVIG, with the exception of the donor selection step. The plasma used for the manufacture is drawn from donors who have high titers of the Ig specificity of interest. The donors may have obtained immunity naturally, through prophylactic immunization, or through targeted immunization for the purpose of becoming a donor of hyper-Ig.[28] Following collection and pooling, donor plasma is fractionated and purified, then undergoes viral reduction steps as described in the section on IVIG production. Hyper-Ig products should contain at least fivefold increased titer of the antibody-specificity of interest, compared to otherwise quantitatively comparable standard preparations of IVIG, according to guidelines established by IUIS/WHO in 1982.[23]

Hyper-Ig products are usually derived from human plasma. Exceptions include several hyper-Ig products for neutralization of venoms or toxins, where immune plasma donors generally are not prevalent in the population, and the risk for adverse consequences on active immunization of volunteer donors is too high. Instead, hyper-Ig products directed toward such targets are derived from plasma from animals immunized against these substances.

Clinical Considerations

The rational for the therapeutic use of polyclonal Ig products is based on the paramount importance of Ig in immunity. Thus, in patients with acquired or congenital Ig deficiency (e.g., hypo- or agammaglobulinemia), these products are aids to globally supplement or replace the missing antigen-specific humoral effector components of the deficient immune system. Such treatment protects these patients against their otherwise increased susceptibility to infections. In other groups of patients, disease is caused by dysregulation of the immune system, pathology often being mediated by the activity of autoantibodies. Polyclonal Ig products, by causing immunomodulation, can provide alleviation of the disease in such patients. The mechanisms of Ig-induced immunomodulation are incompletely understood (see below). IVIGs are currently the products most often used, both for global Ig replacement and for Ig-induced immunomodulation, although hyper-Ig products can also be used for these purposes.[29] However, hyper-Igs have been developed with antigen-specific purposes in mind and are the products of choice for transfer of specific passive immunity for a variety of conditions, as described below.

Mechanism of Action

IVIG

IVIG preparations typically are prepared from plasma pools representing many thousands of human donors. Given the capability of the individual human immune system to produce an estimated up to 10^8 different antibody specificities toward unique antigen epitopes,[30] IVIG products contain a diverse collection of antibody specificities indeed. Therefore, it is not surprising that the mechanisms by which IVIGs exert their effects are incompletely understood.

Some of the known or possible mechanisms are[15,31] (1) classical elimination of opsonized infectious organisms by antibody-dependent cell-mediated cytotoxicity (ADCC) or by complement activation followed by lysis, (2) neutralization of soluble infectious proteins by immunocomplex formation and elimination through the reticuloendothelial system (RES), (3) anti-idiotypic regulation of autoreactive B lymphocytes or antibodies (IVIG contains a broad array of anti-idiotype autoantibodies that can interact with these cellular or humoral autoreactive agents), and (4) "Fc-receptor blockade," which can block clearing of autoantibody-opsonized cells (e.g., platelets in idiopathic thrombocytopenic purpura).

The first two of these mechanisms are important in conferring protection by IVIG to patients with humoral immunodeficiency. The last two are mechanisms by which IVIG causes broad immunomodulation.

HYPER-IG

Hyper-Igs contain high concentrations of Ig against specified antigens. Selected opsonized cellular targets are lysed through complement activation or by ADCC,[15,31] whereas soluble target antigens are bound in immunocomplexes and then eliminated by the RES. Because hyper-Igs are polyclonal Igs, they exert immunomodulation through the same mechanisms listed above for IVIG.

IVIG Products

IVIG products typically are used as either direct replacement of immunoglobulins (for primary or secondary immunodeficiencies) or for their immunomodulatory activity.

IVIG is available in liquid or lyophilized forms. The liquid form is convenient; however, the lyophilized form can be reconstituted to different concentrations and osmolalities as needed for each clinical situation.[32] The lyophilized form can be reconstituted with sterile water, 5% dextrose, and 0.9% saline; however, not all brands can be reconstituted with all diluents. No other medications or fluids should be mixed with the IVIG.[32]

When choosing which IVIG product to use, differences in product composition, such as the concentration of additives, IgA content, osmolarity or osmolality, and pH, should be considered (Table 22–2). The different processing methods can also impact the Ig content and function of the product (e.g., the use of solvent detergent treatment reduces the amount of IgG in the product).[15] However, the antibody titers and biological functions of the immunoglobulin preparations are not typically tested, making it more difficult to compare IVIG products.[15]

Despite the potentially clinically significant differences in the products, many hospital pharmacies stock only one formulation of IVIG, which is then used universally in the treatment of patients in the hospital. Only one randomized, double-blind, multicenter study has compared two different products. The study found that an IVIG prepared using caprylate/chromatography (Gamunex) prevented more validated sinopulmonary infections in patients with primary immunodeficiencies than did a solvent detergent–treated IVIG (Gamimune N, 10% which is no longer produced).[33]

Alternative Ig formulations have been developed for IM, IV, subcutaneous (SC), and oral administration. Only IM and IV products have been approved by the FDA, but the IV product dominates the market mainly owing to

Table 22–2 **Variables to Consider When Choosing an IVIG Product**

Variable	Clinical Significance
Sucrose	The FDA issued a warning letter stating that the administration of IVIGs containing sucrose may increase the risk of development of acute renal failure.[89]
Sorbitol	Patients with hereditary fructose intolerance who receive sorbitol- or fructose-containing solutions may develop irreversible multiple organ failure.
Glucose	Use caution when using glucose-containing preparations in patients with diabetes or renal dysfunction and in the elderly.
Glycine	Glycine-containing IVIG products are associated with increased frequency of vasomotor events.
Maltose	Some blood glucose monitoring systems may interpret maltose as glucose and give falsely elevated results, which can result in an iatrogenic insulin overdose.
Sodium	The concentration of sodium in the product is dependent on the concentration to which the product is reconstituted and the diluent used for reconstitution. Caution should be used when products with high sodium concentrations are given to patients with heart failure or renal dysfunction, neonates, young children, the elderly, and those at risk for thromboembolism.
pH	Use caution when administering low pH products to patients with compromised acid-base compensatory methods such as neonates or patients with renal dysfunction. There are reports that low-pH preparations may be associated with thrombophlebitis.
Osmolality and osmolarity	The osmolality and osmolarity of the product should be taken into account when treating patients with heart disease or renal dysfunction and for young children, the elderly, and those at risk for thromboembolism.
Volume	Use caution when infusing IVIG to volume-sensitive patients. Some formulations can be diluted to various concentrations, but when a smaller volume is used, the trade-off is that the osmolarity of the solution increases. Some volume-sensitive populations include patients with renal dysfunction and heart disease, the elderly, neonates, and small children.

advantages in dosing.[34] SC administration is an off-label use but may be helpful when venous access is difficult and offers the convenience of home self-administration by the patient. When IVIG and SC Ig therapy were compared in a randomized trial, there were no significant differences in clinical efficacy or in the incidence of adverse reactions.[35] Oral Ig preparations have also been developed and have been administered experimentally with the intent of neutralizing pathogenic microorganisms in the gastrointestinal tract; however, current evidence does not support their routine use.[36,37]

THERAPEUTIC USES

Because of the differences in preparation procedures, the FDA requires that each company demonstrate the efficacy of its product in clinical trials for each indication.[15] IVIG is generally used to either replace antibodies (in primary or secondary immunodeficiency syndromes) or as an immunomodulatory agent in autoimmune disorders. Table 22–3 lists the FDA-approved indications for each product along with the manufacturer's recommended dose. The high-dose regimens are not recommended for volume-sensitive patients. Although each IVIG preparation has not been approved by the FDA for all of the six uses, many clinicians use the preparations interchangeably. Besides the FDA-approved uses, IVIG has a wide variety of off-label uses. It is estimated that more than half of the IVIG prescribed annually is for a non-FDA-approved indication.[38]

FDA-Approved Indications

Primary Immunodeficiency Syndromes. Primary immunodeficiency syndromes are genetically determined disorders that may affect humoral immunity, cellular immunity, phagocytosis, complement function, or a combination of immune activities.[39] Disorders affecting specific humoral immunity (e.g., common variable immunodeficiency, X-linked agammaglobulinemia, and severe combined immunodeficiency) can result in decreased levels of IgG through disorders in B-cell differentiation or in antibody production and can predispose patients to recurrent sinus infections, otitis media, and bronchiectasis. Encapsulated bacteria such as *Streptococcus pneumoniae*, *Neisseria meningitidis*, and *Haemophilus influenzae* are usually the causative agents.[39] Prophylactic administration of immunoglobulins has been the mainstay of therapy to reduce the number and duration of infections.[39] The typical maintenance dose for adults is 400 to 600 mg/kg IVIG at monthly intervals.[5–13]

A study comparing high-dose (600 mg/kg every 4 weeks for adults or 800 mg/kg every 4 weeks for children) and low-dose (300 mg/kg every 4 weeks for adults or 400 mg/kg every 4 weeks for children) IVIG therapy found that high-dose therapy reduced the number and duration of infections.[40] No target serum IgG trough level has been established; however, a trough level of greater than 500 mg/dL was more protective against infection than a trough level of less than 500 mg/dL in one study.[41] Patients with active infections may require more frequent IVIG administration until the infection is cleared, followed by maintenance replacement therapy.[39,40,42] The use of IVIG and antibiotics in patients with primary immunodeficiency syndromes has significantly reduced the incidence and duration of infections in these patients, markedly improving their quality of life.

Secondary Immunodeficiencies. Secondary immunodeficiency syndromes are acquired disorders of the immune system, which may be caused by a hematologic malignancy, by an infection, or by immunosuppressive therapy. IVIG is approved by the FDA in the treatment of secondary immunodeficiencies caused by chronic lymphocytic leukemia (CLL), HIV infection, and immunosuppressive therapy related to bone marrow transplantation.

Table 22–3 **Recommended Doses for FDA-approved Indications for IVIG[5–13]**

Product	Primary Immunodeficiency	ITP	Secondary Immunodeficiency Due to CLL	Pediatric HIV Infection	Prevention of GVHD and Infection in Adult BMT	Kawasaki Syndrome
Carimune	200 mg/kg once a month; dose may be increased to 300 mg/kg, or frequency of dosing may be increased	400 mg/kg for 2–5 consecutive days. If platelet count does not respond, a single infusion of 400 mg/kg may be given. If response is still inadequate, a single infusion of 800–1000 mg/kg may be given.	×	×	×	×
Flebogamma	300–600 mg/kg body weight every 3–4 weeks	×	×	×	×	×
Gammagard S/D	300–600 mg/kg body weight every 3-4 weeks	A single dose of 1000 mg/kg. The need for additional doses can be determined by clinical response and platelet count. Up to three separate doses may be given on alternate days if required.	400 mg/kg every 3–4 weeks	×	×	Either a single 1000 mg/kg dose or a dose of 400 mg/kg for 4 consecutive days beginning within 7 days of the onset of fever. Also administer aspirin therapy (80–100 mg/kg/day in four divided doses)
Gammagard liquid 10%	300–600 mg/kg every 3–4 weeks	×	×	×	×	×

Gammar-P IV	Children and adolescents: starting doses of 200 mg/kg every 3 to 4 weeks Adults: 200 mg/kg to 400 mg/kg given every 3–4 weeks	×	×	×	×	×
Gamunex	300 and 600 mg/kg every 3–4 weeks	Either two doses of 1000 mg/kg given on consecutive days, or five doses of 400 mg/kg given daily for 5 days	×	×	×	×
Iveegam EN	200 mg/kg per month; the dose may be increased up to fourfold, or intervals between infusions can be shortened	×	×	×	×	Either 400 mg/kg daily for 4 consecutive days or a single dose of 2000 mg/kg given over a 10-hour period within 10 days of disease onset. Also, a dose of 100 mg/kg of aspirin should be administered daily through the 14th day of illness, then 3–5 mg/kg each day for 5 weeks
Octagam	300–600 mg/kg every 3–4 weeks	×	×	×	×	×

×, not an FDA-approved indication.

Hypogammaglobulinemia Associated with CLL. The use of prophylactic IVIG in patients with hypogammaglobulinemia associated with CLL has been shown to prevent recurrent bacterial infections.[43] Several studies have demonstrated that low-dose IVIG (250 mg/kg every 4 weeks in two studies[44,45] or 10 g every 3 weeks in another study[46]) is as effective as high-dose IVIG (400 mg/kg every 3 weeks) therapy in preventing infection. Although IVIG is approved by the FDA to treat hypogammaglobulinemia associated with CLL, there has been debate regarding the cost effectiveness of this measure.[47]

HIV Infection. Patients with advanced HIV infection demonstrate defects in cellular and humoral immunity, making them susceptible to life-threatening infections. In the early to mid-1990s, studies demonstrated that prophylactic IVIG administration in children with advanced HIV infection was associated with a decrease in the number of severe bacterial infections.[48] Spector and colleagues randomly assigned 255 children who were being treated with zidovudine to receive either 400 mg/kg IVIG or a placebo monthly and examined the 2-year rate of bacterial infections. The group concluded that, for children with advanced HIV disease treated with zidovudine, IVIG decreased the incidence of serious bacterial infection only in children who were not also receiving prophylactic trimethoprim-sulfamethoxazole.[49]

Studies conducted in the mid-1990s examining the use of prophylactic IVIG in adults with advanced HIV infection yielded conflicting results in terms of protection against infection and reduction of hospital stays.[50,51] However, no studies of IVIG effectiveness have been conducted in children or adults receiving more recent therapies such as HAART and prophylactic trimethoprim-sulfamethoxazole, so the benefits of adding IVIG to current treatment protocols are unknown.[48]

Allogeneic Bone Marrow Transplantation. Patients who have undergone bone marrow transplantation and immunosuppression are at risk for infectious complications. Several studies[52,53] have shown that allogeneic bone marrow transplant recipients who received IVIG experienced a reduction in graft-versus-host disease (GVHD) and transplantation-related mortality in the first 90 days after transplant. Monthly treatment from 90 days to 1 year post-transplantation resulted in no significant differences versus placebo in survival, incidence of obliterative bronchiolitis, severity of airflow obstruction, and incidence of or mortality due to chronic GVHD. In addition, treated patients experienced delayed humoral recovery.[54]

Because of the high cost of IVIG therapy, more recent studies have focused on finding the minimal IVIG dose necessary to reduce GVHD and transplantation-associated mortality. A 1999 study by Abdel-Mageed and coworkers found that patients receiving 250 mg/kg weekly from day −8 to day +111 did not differ significantly from patients receiving a 500 mg/kg course of IVIG in terms of event-free survival and frequency of infection. However, patients receiving the higher dose of IVIG had less acute GVHD.[55] In a multicenter, randomized, double-blind trial by Winston and colleagues, patients received either 100 mg/kg, 250 mg/kg, or 500 mg/kg doses of IVIG weekly for 90 days and then monthly until 1 year after transplantation. All three groups were similar in the incidence of chronic GVHD, type and frequency of infection, relapse of hematologic malignancy, and survival. As demonstrated in previous studies, there was less acute GVHD in patients treated with higher dose IVIG.[56] Because of the high cost of treatment and because IVIG has been associated with a delay in recovery of recipient humoral responses, the clinical benefit of IVIG use in bone marrow transplant recipients is questionable and may even delay engraftment.[54]

Immune Dysregulation

Idiopathic Thrombocytopenic Purpura. Idiopathic thrombocytopenic purpura (ITP) is caused by the removal of auto-antibody-coated platelets by the RES. Practice guidelines from the American Society of Hematology do not recommend treating patients with ITP whose platelet counts are >50,000/μL.[57] When the platelet count is significantly decreased and treatment is indicated, glucocorticoids are the first-line therapy. When steroids are contraindicated or are ineffective, RhIG may be used in Rh-positive individuals who have a spleen (see Hyper-Ig section). IVIG is reserved for patients with platelet counts <50,000/μL who have severe, life-threatening bleeding or are refractory to initial therapy. Because the response to IVIG is rapid but temporary, the use of IVIG is typically reserved for situations in which the platelet count needs to be raised quickly, such as prior to surgery or during an acute hemorrhage.[57–59] In children with ITP, treatment is usually not required if the platelet count is >30,000/μL or if the patient is asymptomatic or has minor purpura.[59] IVIG may be used as initial therapy in children with platelet counts <10,000/μL and minor purpura, for children with platelet counts <20,000/μL and mucous membrane bleeding, and to treat severe, life-threatening bleeding.[57]

Kawasaki Disease. Kawasaki disease, also known as mucocutaneous lymph node syndrome, is an acute, self-limited childhood disorder manifested by fever, bilateral conjunctivitis, erythema or drying or fissuring of the lips and oral mucosa, edema or erythema of the peripheral extremities, rash, and cervical lymphadenopathy.[60] The etiology of Kawasaki disease is unknown, but the presentation and course of the disease, its occurrence in young children (median age of 2 years in the United States), the pattern of spread within a community, and the winter-spring seasonality of outbreaks suggest an infectious etiology. However, no microbial agent has been identified. An alternative hypothesis is that Kawasaki disease is an immunologic response to an infectious agent.[60]

For unknown reasons, Kawasaki disease is associated with systemic vasculitis. One of the most concerning complications of the disease is the development of coronary artery aneurysms in 15% to 25% of untreated children.[60] The vasculitis begins with endothelial cell swelling and subendothelial edema. Around 7 to 9 days after onset of the disease, the vessels are invaded by neutrophils and then by mononuclear cells, CD8+ T cells, and IgA plasma cells, resulting in destruction of the internal elastic lamina. This is ultimately followed by scar tissue formation.[60]

To prevent coronary artery complications, the American Heart Association Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease recommends the administration of daily doses of 80 to 100 mg/kg of aspirin along with IVIG.[60] Some clinicians reduce the dose to 3 to 5 mg/kg/day after the child has been afebrile for 48 to 72 hours, whereas others wait until day 14 of illness and 48 to 72 hours after the fever has subsided. If there is no evidence of coronary changes by 6 to 8 weeks after the onset of illness, the low-dose aspirin may be stopped, but if coronary abnormalities develop, aspirin might be continued indefinitely. A single infusion of 2 g/kg of IVIG is given with aspirin within 7 days of illness if possible.

Children treated before day 5 of illness are no more likely to develop cardiac abnormalities than are those treated on days 5 or 7 of illness. Children presenting after day 10 of illness who demonstrate persistent fever without other explanation or aneurysms and ongoing systemic inflammation are also treated with IVIG.[60] The mechanism by which IVIG prevents coronary artery complications is unknown, but some hypotheses include the neutralization of microbial agents and/or the modulation of immune activities including cytokine production, the downregulation of antibody production by B cells, and the modulation of T-cell activity.[60]

Off-Label IVIG Use

Hypogammaglobulinemia Associated with Multiple Myeloma. There is evidence that prophylactic IVIG use in patients with plateau-phase multiple myeloma is effective in preventing infection.[48] In a double-blind, multicenter trial, [82] patients with plateau-phase multiple myeloma were randomized to receive either 400 mg/kg of IVIG or a placebo monthly for 1 year. The patients receiving IVIG experienced significantly reduced incidence of recurrent infections.[61] A second study examined 25 patients with multiple myeloma and polyclonal immunoglobulins below the lower limit of normal or a recent history of recurrent infections. In the 2-year cross-over study, patients either received 300 mg/kg IVIG or no therapy. The data suggested that IVIG could be beneficial in preventing serious infections.[62]

Neonatal Prophylaxis and Treatment of Sepsis. Because maternal IgG crosses the placenta in the last 4 to 6 weeks of pregnancy, preterm infants have lower levels of maternal IgG and are more susceptible to infection compared with term infants. Although initial studies demonstrated clinical benefit in preterm infants treated with prophylactic IVIG, a subsequent randomized, controlled trial of 2400 preterm infants showed no evidence that IVIG prevented infections shortterm or long term or improved mortality.[63] A 2004 meta-analysis conducted by Ohlsson and Lacy also demonstrated no clinical benefit in terms of morbidity or mortality,[64] so the routine use of prophylactic IVIG in preterm neonates is not recommended.

Although the use of IVIG as adjuvant to antibiotics in the treatment of neonatal sepsis was associated with reduced mortality and a more rapid recovery in one study,[65] a meta-analysis conducted by Ohlsson and Lacy that examined administration of IVIG for suspected or subsequently proved infection in neonates did not find a statistically significant decrease in mortality for neonates treated with IVIG.[66]

Sepsis and Septic Shock in Adults. A meta-analysis of 27 clinical trials compared the use of IVIG versus placebo or no treatment on outcome in patients with bacterial sepsis or septic shock. Outcome measurements were mortality, bacteriologic failure rates, and duration of stay in hospital. Mortality was significantly reduced in patients who received IVIG; however, the number of patients studied was small.[67] Although the use of IVIG for sepsis or septic shock seems beneficial, further studies should be conducted before its routine use can be recommended.

Severe Anemia Due to Parvovirus. Parvovirus usually has only mild effects in immunocompetent individuals, but in the immunocompromised it may cause severe anemia and reticulocytopenia. Immunocompromised patients infected with parvovirus who receive IVIG experience an increase in hematocrit to greater than 40% and a resolution of symptoms.[68] The use of IVIG should be considered in this clinical situation.

Organ Transplantation. A retrospective study showed that the incidence of cytomegalovirus (CMV) infection in renal transplant patients treated with ganciclovir while in the hospital followed by 3 months of acyclovir was not significantly different from that of patients who received acyclovir followed by IVIG.[69] The subset of patients treated with gancyclovir who were CMV seronegative and who received a transplant from a CMV-seropositive donor had a lower incidence of CMV infection compared with the group receiving IVIG, so IVIG may be helpful in this situation.[69] Given the equivocal results of comparisons of antiviral agents with IVIG and given its expense and adverse effect profile, the use of IVIG in this situation is controversial.48 Early studies suggested that IVIG prophylaxis was beneficial in heart and lung transplantation; however, IgG-CMV-enriched preparations have not demonstrated benefit in heart and kidney transplant recipients.[70,71] Studies with a limited number of patients have suggested that IVIG could help reverse allograft rejection, but routine use of IVIG in this situation is not recommended.[72,73] IVIG has not shown consistent benefit when given to prevent infection in patients who have undergone solid organ transplant.

Post-transfusion Purpura. Post-transfusion purpura occurs when a person with an antiplatelet antibody is transfused with platelets expressing the corresponding antigen.[74] A sudden drop in platelet count occurs 5 to 14 days after transfusion. Post-transfusion purpura most commonly occur in women whose platelets do not express the HPA-1a (PlA1) platelet antigen and who have developed anti-HPA-1a antibodies through exposure due to pregnancy. The disease is usually self-limited, but life-threatening bleeding can occur and can be treated with high-dose IVIG (400 mg/kg/day) therapy, which produces a rapid increase in platelet count.[74]

Neonatal Alloimmune Thrombocytopenia (NAIT). NAIT occurs when maternal antibodies cross the placenta and destroy fetal platelets. The antibodies are usually directed toward an antigen inherited from the father (usually the Pl_{A1} antigen), which is not present on maternal platelets.[75,76] Several small studies have demonstrated an increase in fetal platelet counts when IVIG was administered. None of the patients experienced intracerebral hemorrhage (ICH).[75,76]

Multiple Sclerosis. A recent review of the seven studies in which IVIG was used to treat patients with relapsing-remitting sclerosis found that IVIG reduced the mean number of annual exacerbations and reduced disability.[77] Similarly, a Cochrane review of two randomized trials also concluded that the administration of IVIG resulted in a reduction in relapse rate and increased time to first relapse during treatment with IVIGs.[78] However, the Cochrane review points out that the number of available studies is limited and encourages future investigators to consistently use MRI findings and evidence of disease progression as end points.[78]

Chronic Inflammatory Demyelinating Polyradiculoneuropathy. Chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) is a neurologic disorder caused by demyelination of the peripheral nerves that results in weakness and impaired sensation in the extremities. Although initially several double-blind studies[79,80] showed that IVIG stabilized symptoms and induced remissions compared with placebo in patients with CIDP, a meta-analysis involving 170 patients receiving IVIG versus placebo, plasma exchange, or

corticosteroids that examined patient outcome in terms of disability score, the Medical Research Council sum score, electrophysiologic data, or walking distance demonstrated no statistically significant difference in outcome when patients were treated with IVIG versus plasma exchange and oral prednisolone. The decision to use IVIG versus steroids or plasma exchange as the first-line therapy can be made on an individual basis keeping in mind the pros and cons of each treatment.[81]

Guillain-Barré Syndrome. While some initial studies[82] reported clinical benefit in patients receiving IVIG for the treatment of Guillain-Barré syndrome, a Cochrane meta-analysis comparing a seven-grade disability scale in Guillain-Barré patients receiving IVIG versus plasma exchange 4 weeks after randomization found no statistically significant difference in the two treatments. The Cochrane review urges that more trials be conducted to determine the optimal dose of IVIG required for treatment. When deciding between the use of IVIG and plasma exchange, cost and availability have to be considered.[83]

Myasthenia Gravis. A meta-analysis of four studies compared short-term patient benefit when IVIG was administered compared with no treatment, placebo, or plasma exchange. None of the trials showed a significant difference between the treatments.[84] Currently, evidence does not support the routine use of IVIG for this indication.[84]

Multifocal Motor Neuropathy. A meta-analysis of four studies compared disability, strength, or conduction block in patients with multifocal motor neuropathy when IVIG was used versus placebo.[85] The analysis, which included 34 patients, showed that IVIG was associated with an increase in strength. Disability was improved but not significantly so. Because of the limited number of patients studied, there is currently not enough evidence to recommend the routine use of IVIG for this indication.[85]

IVIG INFUSION

For patients not previously exposed to IVIG, the initial rate of infusion is typically set at a rate such as 0.01 mL/kg/min for the first 30 minutes (using the lowest available concentration, usually 5%) and is gradually increased, with a rate in the range of 0.03 to 0.06 mL/kg/min tolerated by most adults.[5–13] Package inserts typically recommend a maximum infusion rate in the range of 0.06 to 0.10 mL/kg/min. Slow infusion rates are used for patients who have never been treated with IVIG, patients who are being treated with a different brand of IVIG than received previously, and patients who have not been exposed to IVIG in more than 8 weeks.[32] Patients at increased risk of developing renal insufficiency or thrombosis are also treated with slow infusion rates. Vital signs are monitored every 15 minutes for the first hour and every 30 to 60 minutes thereafter until the infusion is complete. The common adverse reactions occurring during infusion include headache, nausea, vomiting, chills, fever, and malaise and seem to be related to the rate and dose of infusion.[32]

About 90% to 98% of the protein content of IVIG is IgG.[5–13] The serum IgG level peaks immediately after infusion and drops to 40% to 50% of this level approximately 1 week later.[10] The mean half-life of the product is approximately 3 to 4 weeks, but the half-life varies according to the patient population being treated.[15] Because of the presence of small amounts of IgA, IgA-deficient patients could experience an anaphylactic reaction upon exposure to IVIG.[5–13] Epinephrine should be available during infusion in case an anaphylactic reaction occurs.

SPECIAL CONSIDERATIONS

Isohemagglutinins. The cold ethanol fractionation manufacturing process leaves only trace amounts of blood group isohemagglutinins in immunoglobulin preparations. Thus, the process abrogates the need for ABO and Rh testing before administration of the product. Because of the presence of low titers of IgG anti-A and anti-B antibodies in Ig preparations, their administration may cause a positive direct antiglobulin test[86] and may lead to low-grade hemolysis after high-dose IVIG therapy.[87,88]

False-Positive Serologic Testing. Caution should be used when interpreting serologic results from recipients of IVIG because the Ig infused via the IVIG product can cause false positives.[15] The presence of a suspected infection in a patient receiving IVIG may be confirmed using methods other than serologic testing such as PCR or by repeating serologic testing several weeks after the initial test and watching for an increase in titer.[15]

Risks for Acute Renal Failure. In 1999, the FDA distributed a letter alerting health care providers to reports associating IVIG use with renal dysfunction and acute renal failure.[89] Baseline blood urea nitrogen (BUN) and serum creatinine measurements should be drawn prior to the initiation of IVIG therapy and monitored periodically after the infusion. If patients develop signs of renal dysfunction, discontinuation of IVIG should be considered. Since sucrose-containing preparations have been most commonly implicated, these preparations should either not be used in those at risk or should be infused at a maximum rate of 3 mg sucrose/kg/min to well-hydrated patients.[89]

Hyper-Ig

The passive administration of Igs has been used to treat infectious diseases since the late 1800s.[16] With the advent of antibiotics, Igs were used less frequently; however, they continue to play a role in the prevention and treatment of infectious diseases. Hyper-Igs are concentrations of high titers of specific antibodies produced from the plasma of actively immunized individuals or from immunized animals (e.g., bovine, equine).

Although the majority of hyper-Ig formulations are used to treat infectious diseases, preparations are also available to prevent Rh alloimmunization, to modulate immune function, and to neutralize toxins and venoms.[21] The following sections discuss the clinical use of hyper-Ig.

HYPER-IG FOR THE TREATMENT OF INFECTIOUS DISEASES

Hepatitis A. Human plasma–derived hepatitis A Ig is obtained from donors who have obtained immunity naturally, prophylactically, or through targeted volunteer programs.[25] The Ig is administered to travelers who plan to travel to an endemic area for hepatitis A, to individuals after exposure, and to infants born to mothers infected with hepatitis A. However, the most effective method of prevention is vaccination prior to travel. A dose of 0.02 mL/kg of hepatitis A Ig is 85% to 90% effective in preventing clinical hepatitis when given prior to or within 2 weeks of exposure to the virus.[21]

Hepatitis B. A 0.06 mL/kg dose of hepatitis B Ig (HBIG) is administered to individuals who have been exposed to the virus by needle stick, sexual activity, or mucous membrane exposure. This Ig is prepared from donors with high anti-HBsAg who have obtained immunity naturally, prophylactically, or through targeted volunteer programs[25] and is 80% to 90% effective in preventing infection if given prior to or within 24 hours of exposure. It is also recommended that a 0.5-mL dose of HBIG be administered to infants born to hepatitis B–positive mothers. Studies have also shown benefit when HBIG and antiviral agents are administered for at least 6 months to prevent the recurrence of hepatitis B in liver transplant recipients.[21]

Respiratory Syncytial Virus (RSV). RSV-IGIV is a hyper-Ig produced from human donors with high titers of RSV-neutralizing antibody as determined by a proprietary assay. Alternatively, palivizumab, an MAB directed against the RSV surface F glycoprotein, may be used as prophylaxis against RSV.[21] Although not useful in treating RSV infection, both RSV-IGIB and palivizumab reduce RSV hospitalizations. Palivizumab is the preferred product because it is less expensive and is given intramuscularly instead of intravenously.[21] The American Academy of Pediatrics recommends that RSV prophylaxis be considered during RSV season for high-risk groups including children younger than 2 years old with chronic lung disease who have required treatment in the last 6 months, infants born at less than 32 weeks of gestation, and possibly children with congenital or acquired immunodeficiency.[21,90]

Cytomegalovirus. CMV Ig (CMVIG) is produced from individuals who are naturally immune to CMV with a high antibody titer.[25] CMV infection is of particular concern in patients who have undergone bone marrow transplantation or solid organ transplantation. Although a 1994 meta-analysis showed a decreased incidence of CMV lung infections as well as other symptoms related to CMV when patients were given anti-CMV Ig preparations,[91] subsequent studies of prophylactic IVIG or hyper-Ig CMV-IG to prevent CMV infection after bone marrow transplantation have yielded conflicting results. Studies of the co-administration of CMVIG and antiviral therapy to patients after solid organ transplantation for prophylaxis against CMV infection also have failed to show a clear benefit. Although used by some centers for high-risk patients, CMVIG preparations are not recommended as post-transplant prophylaxis at this time.[48,92,93] Some investigators have reported that the intraperitoneal administration of CMVIG to CMV-infected fetuses may be associated with clinical benefit.[21]

Varicella-Zoster Virus (VZV). VZV Ig is obtained from naturally immunized donors with high titer anti-VZV antibody titers.[25] A dose of 125 U/10 kg (minimum dose of 125 U and maximum dose of 625 U) is used to prevent or modify disease in immunocompromised adults or in adolescents or children who have not been vaccinated. VZVIG is most effective when given within 96 hours of exposure, but it also demonstrates effectiveness when given up to 10 days postexposure. VZVIG is also administered to infants whose mothers develop varicella between 5 days before and 2 days after delivery, infants born at less than 28 weeks of gestation or weighing less than 1000 g at birth if exposed, or infants born at greater than 28 weeks of gestation if exposed and the mother is seronegative.[21,94,95]

Rabies. Rabies Ig (RIG) is a hyper-Ig derived from human donors who have been immunized either prophylactically or through a targeted immunization program.[25] A 20 IU/kg dose of RIG is administered along with rabies vaccine to patients beginning up to 7 days after exposure. In addition, sterile saline is used to make a two- to threefold RIG dilution that is used to infiltrate the wound.[21,96–98]

Measles. A 0.25 mg/kg dose of human plasma–derived Ig for healthy individuals and a 0.5 mg/kg dose for immunocompromised patients is used to prevent or modify measles in infants younger than 1 year, nonimmunized pregnant women, and immunocompromised patients within 6 days of exposure.[21]

Vaccinia. Human vaccinia Ig is obtained from donors who have been immunized with booster immunizations of the smallpox vaccine.[25] Vaccinia Ig intravenous (Human) or VIGIV is used to treat serious complications of smallpox vaccination such as eczema vaccinatum, severe generalized vaccinia, and ocular vaccinia. Although smallpox vaccination is no longer routine, laboratory employees and health care workers who could potentially be exposed to smallpox or a related virus are immunized. Prior to the eradication of smallpox, VIGIV was used to prevent smallpox infection in exposed persons. A 0.6 mL/kg dose divided over 24 to 36 hours is administered IM and may be repeated in 2 to 3 days.[21,99]

PREVENTION OF ALLOIMMUNIZATION WITH RHIG

Licensed for use since 1968, RhIG is a hyper-Ig preparation of anti-D IgG used[1] to prevent alloimmunization resulting from exposure to Rh-positive red blood cells or[2] to treat ITP. The product is derived from human plasma obtained from donors who have natural immunity or who have volunteered to undergo immunization.[25]

RhIG is used to prevent Rh alloimmunization of Rh-negative individuals exposed to the Rh antigen through transfusion or pregnancy.[100] In these situations, the anti-D binds to the Rh-positive red cells, causing their destruction by the RES. This elimination of the highly antigenic Rh-positive red blood cells decreases the probability that the recipient of the red cells will become alloimmunized.

Alloimmunization can be prevented for Rh-negative patients who have received Rh-positive cellular blood products by administering 300 µg of RhIG when the patient has received up to 15 mL of Rh-positive red blood cells.[101–105] When the patient has been exposed to less than 2.5 mL of Rh-positive red blood cells, a dose of 50 µg can be administered.[106] The dose should be administered within 72 hours of exposure to the Rh-positive red blood cells. The 300-µg RhIG dose also is recommended for use in Rh-negative females experiencing abortion or threatened abortion, ectopic pregnancy, abdominal trauma, or obstetric manipulation (e.g., amniocentesis, chorionic villus sampling, percutaneous umbilical blood sampling).[106] Rh-negative pregnant patients also should receive a 300-µg dose as prophylaxis at 26 to 28 weeks' gestation as well as postpartum if the newborn is Rh-positive.[101–105]

MODULATION OF THE IMMUNE SYSTEM

RhIG. RhIG is used to treat ITP in Rh-positive patients with intact spleens. In such cases, the RES works to destroy Ig-coated cells and becomes less able to eliminate platelets.[29] For the treatment of ITP, the initial dose of RhIG is based

on the patient's hemoglobin: 50 µg/kg of RhIG in cases where the hemoglobin is greater than or equal to 10 g/dL, and 25 to 40 µg/kg when the hemoglobin is in the range of 8 to 10 g/dL. Because the administration of anti-D (RhIG) results in a decrease in hemoglobin, it should be used with caution in patients with hemoglobin less than 8 g/dL. Patients who do not respond to the initial dose may receive a second dose of RhIG adjusted for their hemoglobin.[105]

Antithymocyte Ig. Antithymocyte Ig is a preparation of Ig derived from rabbits (Thymoglobulin) or horses (ATGAM) immunized with human thymocytes, resulting in the development of antibodies reacting with human T lymphocytes.[107,108] For the treatment of acute renal graft rejection, a 1.5-mg/kg dose of Thymoglobulin can be given daily for 7 to 14 days or a 10- to 15- mg/kg dose of ATGAM may be given daily for 14 days.[107,108] ATGAM may be used also to delay allograft rejection by giving a 15-mg/kg daily dose for 14 days, beginning just before or after transplantation, followed by a dose given every other day for 14 days. ATGAM can also be used to treat aplastic anemia with a 10- to 20-mg/kg dose given daily for 8 to 14 days.[108]

NEUTRALIZATION OF TOXINS WITH HYPER-IG

Diphtheria. Available through the CDC, diphtheria antitoxin (DAT) produced from horses immunized with diphtheria toxoid administered with antibiotics has proved effective in treating diphtheria.[109] The antitoxin is mixed in 250 to 500 mL of normal saline and administered IV over 2 to 4 hours. Dosages are as follows: 20,000 to 40,000 units for pharyngeal or laryngeal disease of 48 hours duration; 40,000 to 60,000 units for nasopharyngeal disease; 80,000 to 100,000 units for systemic disease of 3 or more days duration or for any patient with diffuse swelling of the neck; and 20,000 to 40,000 for skin lesions when treatment is indicated. Children are treated with the same doses as adults.[109]

Tetanus. Human hyper-Ig preparations of tetanus Ig (TIG) are derived from human donors who have been immunized either prophylactically or who have volunteered to undergo immunization for this purpose.[25] The final product contains no less than 250 tetanus antitoxin units per container using the U.S. Standard Antitoxin as the reference material.[110] A 250 IU intramuscular dose of TIG is administered to patients lacking immunity who sustain a contaminated wound, deep puncture wound, or wound associated with devitalized tissue. A 3000–6000 IU intramuscular dose of TIG is used for active disease. The patient should also be actively immunized at the time TIG is administered.[21,110]

Botulism. Human- and equine-derived botulism antitoxin formulations are available for the treatment of wound botulism or food-borne illness and are available as prophylaxis for individuals who have been exposed through tainted food.[111,112] The human plasma–derived product is obtained from donors immunized with pentavalent botulinum toxoid. The final product contains a titer of 15 IU/mL against type A toxin and 4 IU/mL against type B toxin. A 1- mL/kg intravenous infusion of botulism Ig is recommended for the treatment of infant botulism.[112]

TREATMENT OF DRUG OVERDOSE WITH HYPER-IG

Digitoxin or Digoxin. Ovine-derived digoxin immune Fab can be used to treat the life-threatening effects of digoxin or digitoxin overdose.[113] The administration of digoxin immune Fab is indicated for adult patients who have ingested digitalis doses of greater than 10 mg or pediatric patients who have ingested greater than 4 mg, patients with steady-state serum concentrations greater than 10 ng/mL, and patients with potassium concentrations greater than 5 mEq/L following overdose. Each vial contains 38 mg of digoxin-specific Fab fragments, which can neutralize 0.5 mg of digoxin or digitoxin. When an acute overdose of an unknown amount of digoxin or digitoxin occurs, 20 vials of digoxin immune Fab fragments should be administered to adults or children. In volume-sensitive patients, this may be reduced to 10 vials followed by close monitoring and additional doses if needed. For patients experiencing toxicity due to chronic therapy, a six-vial dose for adults and a one-vial dose for infants and small children is recommended.[113]

TREATMENT OF ENVENOMATION WITH HYPER-LG

Black Widow Spider (*Latrodectus mactans*). Patients with symptoms due to black widow spider bites are treated with black widow spider antivenin, which is obtained from horses immunized with the venom.[114] Adults and children are generally treated with one vial that contains not less than 6000 antivenin units. The dose may be given IM (usually in the anterolateral thigh) or may be diluted in 10–50 mL of saline and given IV over 15 minutes. Although one dose usually causes a resolution of symptoms in 1 to 3 hours, a second dose may be required.[114]

Pit Viper (crotalid). Patients who have been envenomed by pit vipers can be treated with polyvalent antivenin obtained from horses immunized with pit viper venom.[115] Reconstitution of each vial yields a 10- mL solution of antivenin. For minimal exposure to venom, 2 to 4 vials are administered, moderate exposure requires treatment with 5 to 9 vials, and 10 to 15 vials are used to treat severe exposure. The dose is typically given IV but may be given IM. When given IV, the dose is usually diluted 1:1 or 1:10 using sodium chloride. The first 5 to 10 mL are given slowly over 3 to 5 minutes and then increased as tolerated by the patient. The dose is most effective when given within 4 hours of the pit viper bite.[115]

Coral Snake (*Micrurus fulvius*). Antivenin directed against coral snake venom is produced by immunizing horses with venom from the eastern coral snake (*Micrurus fulvius fulvius*).[116] The resulting antivenin also neutralizes Texas coral snake (*Micrurus fulvius tenere*) venom but does not neutralize venom from the Arizona or Sonoran coral snake (*Micruroides euryxanthus*). Each vial is reconstituted to a 10- mL solution. Initial therapy should consist of the administration of 3 to 5 vials of *Micrurus fulvius* antivenin with the initial 1 to 2 mL given over 3 to 5 minutes. The administration rate is increased as tolerated by the patient. Additional doses may be given if needed.[116]

Adverse Reactions

IVIG

Because most adverse reactions associated with Ig infusion are reported as case reports, the true incidence of adverse events associated with Ig administration is unknown. Most reactions are mild, with the most common adverse reactions being headache, fever, malaise, myalgia, nausea, vomiting, chills, blood pressure changes, flushing, rash, diaphoresis, pruritus, bronchospasm, chest pain, back pain, and dizziness.[5–13] These symptoms typically occur as a result of either allergy or the rate of infusion. The most

severe reactions that can occur in response to Ig infusion are anaphylaxis, aseptic meningitis, acute renal failure, and thromboembolism.[15,87]

1. Anaphylaxis can occur owing to the exposure of IgA-deficient patients to the small amount of IgA in the IVIG product. Epinephrine should always be available during IVIG infusion. Some manufacturers keep products with low IgA concentrations on their shelves particularly for the treatment of IgA-deficient patients.[5–13]
2. Another rare and severe reaction is aseptic meningitis, which is characterized by severe headache, nuchal rigidity, drowsiness, fever, photophobia, painful eye movements, and nausea and vomiting. Beginning 6 to 48 hours after infusion, patients with a history of migraine who have received high-dose Ig treatment appear to be most susceptible. The CSF demonstrates pleocytosis and elevated protein. The symptoms are reversible and typically resolve in hours to days.[15,87,88]
3. As mentioned previously, over 100 cases of acute renal failure (including at least 17 deaths) have been associated with the infusion of IVIG, particularly those formulations containing sucrose.[15,87] These patients should be infused slowly and monitored carefully for signs of renal dysfunction.
4. IVIG infusion has been associated with thromboembolic events such as deep venous thrombosis, myocardial infarction, cerebrovascular accidents, and pulmonary embolism and could be related to the increase in viscosity experienced after IVIG administration. Patients receiving large Ig doses at rapid rates, as well as elderly, overweight, or immobilized patients, and patients with cardiovascular disease are thought to be at highest risk for development of this complication.[15,87,88]

In addition to these adverse reactions that can occur with any of the IVIG products, specific adverse effects can occur in relation to individual products. The variables associated with the adverse effects as well as the at-risk populations are listed in Table 22–2.

Hyper-Ig. Because hyper-Igs contain many of the same elements as IVIG, they are associated with the same adverse effects (see above section). Unlike IVIG, because many hyper-Igs may be given IM, soreness at the site of injection may occur. Individual hyper-Ig products also have adverse effects specific to them.

RhIG. Because RhIG results in the destruction of Rh-positive red cells, administration of this hyper-Ig can result in anemia and renal insufficiency.[105] Intravascular hemolysis occurring after RhIG administration resulted in four deaths between May 1996 and April 1999.[105] The package inserts recommend adjusting the dose according to the patient's hemoglobin level.

Antithymocyte Globulin. Because antithymocyte globulin works by clearing human T lymphocytes from circulation, chronic use or overdosage of the drug can result in excessive immuno suppression that can put the patient at risk for infection or lymphoma.[107,108] In addition, the antibodies may crossreact with platelets and neutrophils, causing clearance of these cells. This can be reversed by reducing the dose of the hyper-Ig.

Digoxin Immune Fab. Because this hyper-Ig is used to treat digoxin or digitalis overdose, the abrupt withdrawal of the drug's effects may result in a rapid ventricular response if the patient is being treated for atrial fibrillation or congestive heart failure.[113] The reversal of the effects of digoxin or digitalis by digoxin immune Fab also results in hypokalemia.[113]

Animal-Derived Hyper-Ig. Animal-derived hyper-Igs carry the risk of serum sickness. Sensitivity testing should be conducted prior to their use.

Infectious Disease Transmission

IVIG

The effort to limit viral transmission begins by testing plasma donors for antibodies to HIV-1 and -2, HBsAg, and HCV, as well as performing NAT testing for HCV and HIV. As discussed in the section on commercial production of IVIG, the manufacturers pool the collected plasma and produce IVIG using the cold ethanol fractionation method, which significantly reduces the concentration of viruses (approximately 5 log).[15] The transmission of cell-associated viruses such as CMV, Epstein-Barr virus, and human T-cell leukemia/lymphoma virus type 1 is limited by this process, which results in an acellular product. Each manufacturer then adds additional steps (see Commercial Production) to further limit viral transmission. The transmission of HBV and HIV by IVIG has not been reported. However, by the mid-1990s, HCV had been transmitted by IVIG to over 450 people,[117,118] leading the FDA to require that each manufacturer test its viral reduction and inactivation steps by adding model viruses and testing the viral clearance at the end of each step in processing. Since that time, no additional cases of IVIG-transmitted hepatitis C have been reported.[15] According to package inserts of various IVIG products, the manufacturing process results in an overall viral log reduction of 9.6 to greater than 26 for HIV-1, 6.2 to greater than 16.8 for bovine viral diarrhea virus (a model virus for HCV), and 8.5 to greater than 25 for pseudorabies virus (a model virus for lipid enveloped DNA viruses such as the herpes and hepatitis B viruses). One virus that is difficult to eliminate and has been transmitted via IVIG is parvovirus, which is partially heat resistant and is resistant to solvent/detergent treatment. Although antibodies to parvovirus are valuable as a component of IVIG, their presence also indicates an increased risk for viral transmission, presenting a dilemma for manufacturers. At present, screening for antibodies to parvovirus is not required.[15] One other disease caused by an infectious agent that has caused concern in recent years is Creutzfeldt-Jakob disease. Models developed for prion disease indicate that there is probably a low chance of infectivity by blood transfusion. In addition, the concentration of the infectious agent is reduced by several logs during the manufacturing process.[119,120]

HYPER-IG

Because hyper-Igs are produced using the same methods that are used to produce IVIG, the infectious disease risk is similar (see above).

THERAPEUTIC MAB

The ability to mass produce homogeneous Ig with a single predefined specificity was realized by the adaptation of hybridoma technology for the creation, selection, and expansion of monoclonal cell lines derived from single B lymphocytes.[3]

Table 22–4 **Monoclonal Antibodies Approved by FDA for Therapeutic Uses in the United States**

Category	Subcategory	Composition	Target-Specificity	Generic Name/Trade Name	Main Clinical Application Area	FDA Approval
Murine	Unmodified	IgG2a	CD3	Muromonab-CD3/ Orthoclone OKT3	Immunosuppression (treatment of allograft rejection)	1986
Murine	Conjugate radiolabeled (yttrium 90)	IgG1/κ	CD20	Ibritumomab tiuxetan/ Zevalin	Oncology (treatment of relapsed or refractory low-grade B-cell non-Hodgkin's lymphoma)	2002
Murine	Conjugate radiolabeled (iodine 131)	IgG2a/λ	CD20	Tositumomab-I131/Bexxar	Oncology (treatment of relapsed or refractory low-grade B-cell non-Hodgkin's lymphoma)	2003
Near-Human	Chimeric Fab fragment	IgG1	GPIIb/IIIa	Abciximab/ReoPro	Anti-hemostasis (adjunct to percutaneous coronary intervention, for prevention of cardiac ischemic complications)	1994
Near-Human	Chimeric	IgG1/κ	CD20	Rituximab/Rituxan	Oncology (treatment of relapsed or refractory low-grade B-cell non-Hodgkin's lymphoma)	1997
Near-Human	Chimeric	IgG1/κ	CD25	Basiliximab/Simulect	Immunosuppression (prophylaxis of renal allograft rejection)	1998
Near-Human	Chimeric	IgG1/κ	TNFα	Infliximab/Remicade	Anti-inflammation (treatment of rheumatoid arthritis, Crohn's disease, ankylosing spondylitis, and psoriatic arthritis)	1998
Near-Human	Chimeric	IgG1/κ	Epidermal growth factor receptor (EGFR)	Cetuximab/Erbitux	Oncology (treatment of EGFR-expressing, metastatic colorectal carcinoma in patients who are refractory or intolerant to irinotecan-based chemotherapy)	2004
Near-Human	Humanized	IgG1/κ	CD25	Daclizumab/Zenapax	Immunosuppression (prophylaxis of renal allograft-rejection)	1997
Near-Human	Humanized	IgG1/κ	Respiratory syncytial virus	Palivizumab/Synagis	Anti-infection (prevention of serious lower respiratory tract infection in pediatric patients at high risk for RSV disease)	1998
Near-Human	Humanized	IgG1/κ	HER2	Trastuzumab/Herceptin	Oncology (treatment of metastatic breast cancer that overexpresses the HER2 protein)	1998

Near-Human	Humanized Conjugate immunotoxin (calicheamicin)	IgG4/κ	CD33	Gemtuzumab ozogamicin/ Mylotarg	Oncology (treatment of CD33-positive acute myeloid leukemia in first relapse in patients who are 60 years or older and not candidates for other cytotoxic chemotherapy)	2000
Near-Human	Humanized	IgG1/κ	CD52	Alemtuzumab/Campath-1H	Oncology (treatment of B-cell chronic lymphocytic leukemia (B-CLL) in patients who have been treated with alkylating agents and in whom fludarabine therapy has failed)	2001
Near-Human	Humanized	IgG1/κ	IgE	Omalizumab/Xolair	Allergy (treatment of moderate to severe persistent asthma of adults and adolescents with positive skin test or in vitro reactivity to a perennial aeroallergen and whose symptoms are inadequately controlled with inhaled corticosteroids)	2003
Near-Human	Humanized	IgG1/κ	CD11a	Efalizumab/Raptiva	Anti-inflammation (treatment of adult patients with chronic moderate to severe plaque psoriasis who are candidates for systemic therapy or phototherapy)	2003
Near-Human	Humanized	IgG1	Vascular endothelial growth factor	Bevacizumab/Avastin	Oncology (treatment of metastatic carcinoma of the colon or rectum when used in combination with intravenous 5-fluorouracil-based chemotherapy)	2004
Human	Phage-display	IgG1/κ	TNF-α	Adalimumab/Humira	Anti-inflammation (treatment of rheumatoid arthritis in adult patients with moderately to severely active disease and inadequate response to one or more DMARDs)	2002

Data from refs. 122–124, 130–142, 146.

The products, called monoclonal antibodies (MABs), were predicted to revolutionize drug therapy and the pharmaceutical industry by allowing new ways for selective therapeutic targeting. Using the relatively well-understood IgG molecule as a biocompatible homing device, it was argued, any cellular target accessible via the bloodstream could be reached and selectively targeted for destruction or interference.

The first step is to develop an MAB directed against a molecule that is selectively expressed on the surface of the cell in question (i.e., a molecular flag), regardless of whether the cell is foreign (such as an invading microorganism) or intrinsic (such as a tumor cell) to the body. Once attached to the target, destruction can be achieved by lethal substances attached to the MAB during its pharmaceutical production/formulation, such as radioisotopes or toxins, or by the destructive capabilities of the Ig nature of the MAB, such as complement-fixation or activation of phagocytes via Fc-receptor-dependent opsonization. Similarly, the MAB can inhibit extracellular molecular pathways through neutralization and elimination of soluble molecular targets. In short, the MAB was envisioned as fulfilling Paul Ehrlich's dream of a "magic bullet."

Thus, together with cytokines, MABs were important inspirations for the development of the biotechnology-based drug industry. The *first-generation* therapeutic products were murine MABs. Many went to clinical trials in the early to mid-1980s. It turned out that murine MABs, by and large, had a critical flaw with respect to repeated clinical use: they are detected as foreign by the human immune system.[121] The development of HAMAs dramatically reduced the in vivo half-life of the MAB development compounds in many patients, thereby reducing their effectiveness. Only one of the early lead candidates made it to market: anti-CD3 (OKT3/muromonab), used for the treatment of acute allograft rejection.[122] More recently, two murine anti-CD20 MABs have been approved as radionuclide-labeled conjugates and are used for treatment of refractory or relapsed, low-grade, non-Hodgkin's B-cell lymphoma.[123,124]

One solution to this problem has been to make more "human-like" MABs in order to reduce their immunogenicity. Technologies were refined to achieve this, and *second-generation* candidate therapeutic MABs emerged, including (1) chimeric MABs (human C regions, murine V regions),[125] (2) nonhuman primate MABs,[126,127] (3) humanized MABs (human C regions, humanized V regions (framework region amino acid residues are exchanged for consensus human, whereas murine hypervariable region amino acid residues are maintained),[128] and (4) a combination of 2 and 3, so-called primatized MABs (human C regions, nonhuman primate-based V regions).[129] Thirteen[130–142] of the 17 therapeutic MABs on the U.S. market belong to the second generation, five of which are chimeric[133–136,140] and eight humanized,[130–132,137–139,141,142] and all but one[135] were FDA-approved in the last decade. Table 22–4 presents an overview of these new Ig-products.

Third-generation therapeutic MABs, predominantly still in development, are fully human MAB proteins. Such MABs have been derived in several ways. The earliest intentionally created, completely human MABs were generated from immunized human B lymphocytes obtained from immunized hosts or through in vitro immunization. These B lymphocytes were immortalized either by EBV-transformation or fusion to a nonproducing heterohybridoma,[143] or both. Some antiviral human MABs (e.g., anti-CMV, anti-HBV) of this kind progressed relatively far in clinical trials[144] but ultimately were not brought to market. In addition, this approach to making completely human MABs faced serious challenges when the intention was to address human pharmaceutical targets.

Instead, two other approaches to human MAB-development emerged. One is based on displaying human Ig V-region repertoires on the surface of filamentous phage.[145] Such V-region libraries can be interrogated by antigens allowing affinity selection of interesting V-region candidate genes. In vitro affinity-maturation schemes have been invented, and full Ig-producing cassettes have been developed for resulting expression of selected V regions. A first fully human MAB, directed against the cytokine TNFα, was developed by this technique and has reached the market as an anti-inflammatory.[146]

Another angle to develop fully human MABs to human pharmaceutical targets is the generation of transgenic mice expressing human Ig genes. Such murine models were described by investigators at two California biotech companies in 1994.[147–149] There are now about 30 MABs in clinical testing based on human Ig V-region sequences derived from these transgenic mice.[148]

Overall, the MABs that currently have penetrated the market predominantly focus on targets in immunology/inflammation and oncology. The many MAB candidates in development have a similar profile. Although a detailed clinical profile of each of these MABs is beyond the scope of this chapter, it is predicted that this product line will continue to grow and increasingly intersect with transfusion medicine.[150]

CONCLUSION

A natural defense protein with a good safety profile, Ig derived from pooled human plasma is broadly used to confer passive immunity and to achieve immunomodulation. There are currently six FDA-approved indications for IVIG administration. Because of the expense of the product, the risks involved in IVIG administration, and the lack of studies supporting the growing number of off-label uses of IVIG, the decision to administer IVIG should be made carefully. A recent successful development in the field of Ig therapy is improved technology to produce and develop MABs for a variety of clinical markets. This offers the unprecedented possibility to intentionally and specifically clinically target bioactive mediators and receptors. Owing to the purity, specificity, and limited potential of infectious disease transmission of MABs, they now enjoy a consistently high success rate compared with other pharmaceutical development compounds. MAB products will likely both increase in existing markets and diversify into other applications. Given both the expense and versatility of MAB therapy, transfusion medicine physicians are likely to take an increasing role in consulting about their uses.

Chapter 23

Platelets and Related Products

John M. Fisk • Patricia T. Pisciotto • Edward L. Snyder • Peter L. Perrotta

INTRODUCTION

Platelet transfusion therapy has dramatically improved since the 1950s when whole blood and freshly prepared, platelet-rich plasma were the only available sources of viable platelets. In parallel, technical advances also made over the past several decades have greatly facilitated the collection and storage of platelet concentrates. These include centrifugation procedures optimized to allow the separation of high numbers of functionally active platelets from whole blood donation, and the introduction of automated cell separators now widely used to collect even larger numbers of platelets from a single donor. Initially, the shelf life of platelets was very limited (<1 day) until improved storage containers and optimization of storage conditions allowed for longer (5- to 7-day) storage. This improvement was based on the development of gas-permeable containers that overcame the adverse effects of prolonged storage on platelet structure and function—the "platelet storage defect."

While platelets can be stored for up to 7 days and still have acceptable function and post-transfusion recovery, platelets stored at room temperature were kept only up to 5 days because of the increased risk of bacterial proliferation. However, recent advances in blood collection techniques and automated bacterial culture methodologies coupled with mandatory bacterial testing of all platelets have once again offered the possibility of extended room temperature platelet storage. In addition, many workers continue to investigate alternative techniques to store platelets (e.g., platelet-storage solutions, refrigerated storage) and explore possible platelet substitutes. The latter may be either derived from donor platelets or entirely synthetic.

Platelet transfusions are indicated for the prophylaxis or treatment of bleeding in patients who have low numbers of circulating platelets or functionally inactive platelets.[1] Indeed, thrombocytopenic bleeding was a major cause of death in patients with acute leukemia until stored platelet products became widely available.[2] Today, stored platelets are most commonly transfused to prevent bleeding in severely thrombocytopenic patients. These prophylactic platelet transfusions, largely provided to patients who receive intensive therapies for hematologic malignancies and solid tumors, are primarily responsible for the dramatic increase in the number of platelet transfusions over the past 20 years.[3] Despite the widespread use of platelets in clinical practice, there remains considerable variability in platelet transfusion practices.[4] Part of the difficulty in developing evidence-based guidelines for platelet transfusion therapy is that the relationship between a patient's platelet count and clinically significant bleeding remains only partially understood. Furthermore, the properties of transfused platelets that best correlate with hemostatic effectiveness are not fully defined. These characteristics, which are presumably related to the efficacy of platelet transfusions, are most likely affected by the techniques used to prepare and store platelet concentrates. Thus, despite efforts to standardize platelet transfusion therapy, practices are largely determined locally.

PHYSIOLOGIC ROLE OF PLATELETS

Platelets play a critical role in normal hemostatic processes by preserving vascular integrity and maintaining hemostasis. They accumulate at sites of vascular injury and form hemostatic "plugs." Platelets also participate in clot retraction and wound healing. The effectiveness of platelet transfusion therapy is at least partially explained by the role of endogenous platelets in normal hemostasis. The innate properties of platelets are related to their unique structure, composition, and ability to respond to a variety of stimuli. Their importance in both bleeding and thrombotic conditions has been elucidated over the past several decades. Therefore, one of the goals of transfusion practice is to prepare platelets that maintain these properties during their preparation and storage. Alternatively, novel substances that have many of the hemostatic properties of intact human platelets are being developed as potential alternatives to standard platelet concentrates.

Platelets circulate in the blood as small anucleate, membrane-encapsulated cell fragments. It was recognized in the early 1900s that platelets are derived from bone marrow megakaryocytes.[5] However, the overall process of platelet production, or *thrombopoiesis*, remained poorly understood.[6] Platelets appear on Wright-stained blood smears as small, oval to round bluish-gray bodies containing small purple-red granules. They normally range in size from 1.0 to 2.5 μm, or less than one half the diameter of a normal red cell. The platelet surface is covered by a thin glycocalyx that contains various membrane glycoproteins, mucopolysaccharides, glycolipids, and adsorbed plasma proteins. Sialic acid residues attached to lipids and proteins impart a net negative charge to the platelet surface that may play a role in minimizing the interaction between other platelets and negatively charged endothelial cells. The folded platelet external plasma membrane forms a surface connected canalicular or collecting system that allows plasma components to enter the platelet

and internal granule contents to be released. It also greatly increases the surface area of the platelet. Sodium and calcium ATPase pumps within the plasma membrane are thought to control the platelet's ionic environment.

Platelet Structure

Platelets have a discoid shape when in a resting state. The discoid shape is likely maintained by a network of actin filaments near the plasma membrane and a circumferential band of microtubules composed of tubulin polymers and microtubule-associated proteins.[7] On activation, platelet actin can polymerize into microfilamentous bundles that contribute to platelet shape change. The intracellular signaling events that contribute to platelet adhesion and aggregation are becoming better understood.[8] Platelets contain both organelles found in other cells (lysosomes, peroxisomes) and platelet-specific organelles (dense bodies, α-granules). Electron-dense granules (dense bodies) contain storage pool adenosine diphosphate (ADP), adenosine triphosphate (ATP), serotonin, and a major portion of the platelet's calcium. α-Granules contain a variety of proteins including adhesive proteins (von Willebrand factor [vWF], fibrinogen, fibronectin, thrombospondin, P-selectin), anticoagulants (platelet factor 4, β-thromboglobulins), coagulation factors (factors V, XI, XIII, protein S), and growth factors for angiogenesis and repair (platelet-derived growth factor, transforming growth factor β, thrombospondin).[9] Each platelet contains from 2 to 7 small mitochondria that participate in oxidative metabolic processes and are able to undergo changes that are associated with cell injury and death.[10] α-Granules are the most numerous granules seen in platelets by electron microscopy.

Platelet Proteins and the Platelet Membrane

Platelets contain a large array of proteins; some are taken up into α-granules from plasma, whereas others are platelet specific. The most concentrated platelet-specific proteins include platelet factor 4 (PF4) and members of the β-thromboglobulin family. Both proteins can bind heparin. PF4, in particular, binds heparin with high affinity and can neutralize heparin's anticoagulant activity.[11] Other described activities of PF4 include chemotaxis for neutrophils and monocytes,[12] inhibition of megakaryocyte maturation,[13] potentiation of platelet aggregation in vitro,[14] and widespread immunomodulatory effects.[15]

The platelet plasma membrane serves two important roles in hemostasis: (1) it provides a means for cell-to-cell or cell-to-matrix interactions, and (2) it furnishes a surface that enhances the fluid phase of coagulation. Like other mammalian cells, the lipid bilayer consists of phospholipids (PLs) asymmetrically arranged between the outer and inner leaflets.[16] In a resting state, the outer leaflet is composed primarily of neutral phospholipids (PL, phosphatidylcholine, and sphingomyelin), while the inner leaflet is composed of negatively charged PL (phosphatidylserine [PS] and phosphatidylethanolamine [PE]). An ATP-dependent aminophospholipid translocase has been identified in platelet plasma membranes that rapidly transports PS and PE from the outer to the inner leaflet. Other mechanisms also help maintain the normal plasma membrane PL asymmetry.[17] Upon activation and increased intracellular Ca^{2+} levels, a "flip-flop" in the normal membrane PL distribution occurs that results in an increase in PS and PE exposure on the outer leaflet. This membrane alteration contributes to the procoagulant activity of platelets. Specifically, activated platelets participate in thrombin generation by providing a favorable external surface charge for the prothrombinase complex (X-Va), thereby localizing fibrin generation in close proximity to the platelet plug.[18]

The most important adhesive glycoproteins found in α-granules include fibrinogen and vWF. Presumably, these substances are released after platelets accumulate at sites of vascular injury. Since megakaryocytes do not produce fibrinogen, platelets accumulate fibrinogen from plasma through processes involving the $\alpha_{IIb}\beta_3$ integrin.[19] vWF is synthesized in megakaryocytes and endothelial cells and is stored in platelet α-granules. Platelet stores of vWF are high enough so that transfusion of platelets alone to patients with severe type 3 von Willebrand disease partially corrects their bleeding times.[20] The platelet membrane also contains a number of membrane glycoproteins (GPs), many of which function as adhesive proteins. These include the glycoprotein Ib-IX-V complex (GPIb-IX-V), which acts as a platelet receptor for vWF in platelet adhesion and facilitates the ability of thrombin, at low concentrations, to activate platelets.[21] The $\alpha_{IIb}\beta_3$ complex, also termed GpIIb/IIIa, spans the platelet membrane and is a functional receptor for fibrinogen, vWF, fibronectin, and vitronectin.[22] The glycoprotein Ia-IIa complex (GpIa-IIa, $\alpha_2\beta_1$) is the receptor for collagen,[23] and, finally, glycoprotein Ic-IIa (GPIc-IIa, $\alpha_5\beta_1$) is a receptor for fibronectin. The latter three glycoproteins are considered integrins, which are a large family of related heterodimers grouped based on their β-subunit structure. P-selectin (known as CD62P, GMP-140, and PADGEM) is an integral membrane protein found in α-granules that becomes expressed on the surface of activated platelets after granule release.[24] Also found in Weibel-Palade bodies of endothelial cells, P-selectin is an adhesive protein that mediates the attachment of neutrophils and monocytes to activated platelets.

Adhesion and Aggregation

Platelets normally circulate in a "resting" state without adhering to vessel walls for approximately 9 to 10 days before they are removed, primarily in the spleen. Transfused platelets do not usually circulate for this long. Platelets rapidly respond to appropriate stimuli, such as collagen exposed on denuded endothelium, by first adhering to the subendothelial matrix. They initially undergo physical changes that include assuming a more spherical shape. Platelet membranes then form multiple extended pseudopods, an event that dramatically increases their surface area. Interaction between agonists in the microenvironment and specific receptors on the platelet surface results in the transmission of signals from the outside of the cell to the interior, generating secondary messengers that induce protein phosphorylation and the opening of ion channels.[25] The ability of platelets to aggregate on surfaces coated with type 1 collagen has been utilized in in vitro tests designed to measure the functional capacity of transfused platelets.[26] This testing is currently available using automated methodologies.[27]

Adhesion, the binding of platelets to a nonplatelet surface, is the initial event in the formation of the platelet plug. Shear

forces within the vessel influence the deposition of platelets on exposed endothelium.[28] At high shear stress, as encountered within the microcirculation, the primary adhesive event is mediated by the interaction of the subendothelium-bound vWF with the platelet GPIb receptor. vWF bound to the subendothelial matrix is believed to undergo a conformational change that exposes the binding site for the GPIb-IX-V complex.[29] The binding site for GPIb appears to reside in the A1 domain of vWF. This bond is transient, and the interaction induces a transmembrane flux of calcium ions, which results in a conformational change and activation of $\alpha_{IIb}\beta_3$. Activated $\alpha_{IIb}\beta_3$ binds irreversibly to vWF to allow firm adhesion of platelets to the vessel wall. The activated $\alpha_{IIb}\beta_3$ integrin recognizes and binds to the RGD (Arg-Gly-Asp) peptide sequences of circulating vWF and fibrinogen, resulting in platelet aggregation.[30] At low shear stresses normally found in larger vessels, the role of vWF in platelet adhesion is less significant.

A critical level of ATP is required for each aspect of platelet function, including shape change, aggregation, and the release reaction. ATP is generated, in part, when glucose is metabolized via the glycolytic and oxidative pathways. As platelets are stimulated, an increase in glycolysis and Krebs cycle metabolism serves to replenish depleted ATP. Platelet adhesion does not appear to be an energy-dependent function as very little ATP is consumed during primary adhesion.[31] ATP consumption mainly occurs during the early phases of platelet aggregation (e.g., shape change).[32] Adenine nucleotides present in platelets are found in two pools: ADP in the metabolic pool, which is constantly turning over, and storage pool ADP, which is found in the dense bodies and released during platelet activation. Plasma glucose metabolism generates approximately 15% of the ATP required during normal aerobic storage, largely via glycolytic catabolism to lactate.[33] Oxidative phosphorylation, perhaps utilizing plasma free fatty acids via β-oxidation, contributes the remaining 85%. Clearly, adequate O_2 and CO_2 exchange is important in maintaining aerobic capabilities of stored platelets. If deprived of oxygen, platelets increase lactate production via anaerobic glycolysis in an attempt to compensate for the loss of energy normally derived from oxidative phosphorylation. Thus, the ability to transport gases—mainly O_2—across the platelet storage bag is critical to normal platelet metabolism and to platelet survival during storage.

PREPARATION AND STORAGE OF PLATELETS

Techniques of Platelet Concentrate Preparation

Platelets are prepared from individual whole blood (WB) donations or are collected from a single donor by automated blood cell separators using apheresis technology.[34] Hereafter, the term *WB-derived platelets* (WB-Plts) is used for platelet concentrates made from either platelet-rich plasma or buffy coats (see below) and the term *apheresis-derived platelets* (AD-Plts) for those collected using automated methods from a single donor.

Whole blood is drawn through wide-bore, siliconized needles to minimize platelet and clotting factor activation and is immediately mixed with anticoagulant. Mechanical devices mix blood with anticoagulant as it is withdrawn and monitor collection volume.[35] Then platelet concentrates are prepared from whole blood using either the buffy coat (BC) or the platelet-rich plasma (PRP) methods (Fig. 23–1). The BC method is favored in Europe, whereas the PRP technique is preferred in the United States. In the PRP method, whole blood is first spun at a low speed ($2200 \times g$) for 3 to 4 minutes within 8 hours of collection. The resulting PRP is then spun at a higher speed ($4000 \times g$) for 5 minutes to pellet the platelets. All but about 60 mL of PRP is removed and the pellet is left undisturbed for about 1 hour.[36] The pellet is then resuspended by gentle kneading of the bag or by placing the unit on a platelet agitator.[37] Generally, the platelets smoothly resuspend within several hours after which they are stored under continuous gentle agitation. Research has shown that using a hard spin first to spin the platelets into a buffy coat on a cushion of red cells and then using a slow spin to isolate the platelets from the separated buffy coat yields a platelet product with less evidence of in vitro activation.[38] It is unclear whether differences in the properties of PRP and BC platelets affect in vivo survival and efficacy. Earlier studies suggested that 1-hour and 24-hour platelet increments were similar following transfusion of either product.[39] A more recent study comparing post-transfusion recovery and survival of radiolabeled WB-Plts prepared by the BC and PRP methods suggested equivalent in vitro and in vivo activity.[40]

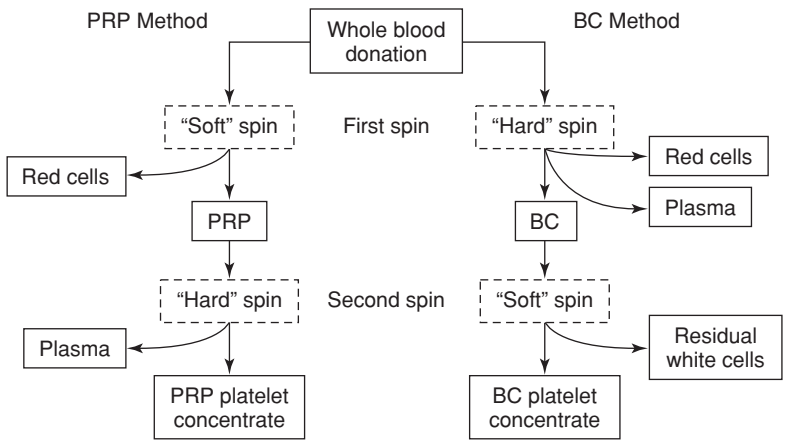

Figure 23–1 Methods for preparation of platelet-rich plasma (PRP)– and buffy coat (BC)–derived platelet concentrates.

Similar studies have compared AD-Plts with BC WB-Plts in terms of their in vitro hemostatic characteristics. Data from these studies support the contention that AD-Plts possess better in vitro hemostatic parameters including preservation of ADP and collagen-induced platelet aggregation and shorter closure times of the PFA 100 test system.[41,42] In vivo studies to ascertain therapeutic differences in these preparations remain to be performed.

Anticoagulant/Preservative Solutions

Citrate-based Storage Solutions

Platelets are prepared from whole blood drawn into one of several anticoagulant-preservative solutions, the most common being citrate-phosphate-dextrose solutions (CPD, CP2D) and CPD with adenine (CPDA-1). Citrate anticoagulates blood according to its ability to chelate calcium and thus inhibit the coagulation cascade. Phosphate serves as a buffer and dextrose as a source of energy. Adenine, which improves red cell survival by increasing cellular ATP levels, serves no purpose in platelet storage. EDTA cannot be used because it causes platelet structural changes associated with reduced in vivo viability and is toxic to humans. Heparin is not an acceptable alternative because it activates platelets, causing platelet clumping. It also causes systemic anticoagulation through its effect on antithrombin. The amount of citrate in the CPD or CPDA-1 preservative does not generally produce systemic anticoagulation or hypocalcemia in blood recipients because it is quickly metabolized to bicarbonate in the liver. AD-Plts are prepared in ACD-A (citric acid, trisodium citrate, dextrose) preservative using automated cell collectors. Citric acid is used to provide a lower pH. In some apheresis systems, platelets are collected as platelet-rich plasma and do not require resuspension, whereas other systems yield a concentrated platelet pellet that must be resuspended. AD-Plts are stored similarly to WB-Plts.

Alternative Storage Solutions

Although platelets stored in citrated plasma are satisfactory for clinical use, several investigators have evaluated other solutions that could extend the shelf life of platelet concentrates or improve their capacity to circulate in vivo after infusion.[43] The majority of these studies have evaluated storage media alternatives in PRP WB-Plts although synthetic storage medium has also been examined for stored BC WB-Plts.[38,44] The scientific basis for this came out of work performed in the 1990s demonstrating that the rate of in vitro platelet aging at 22°C was slowed to less than half of that associated with in vivo aging at 37°C, as determined by isotope labeling.[45] The reduced rate of aging closely paralleled the concomitant reduction in platelet metabolic rate. Thus, in theory, the normal 9- to 10-day platelet life span could be extended to 18 to 20 days or more under optimal storage conditions. Proposed interventional targets to achieve "optimal storage conditions" have included methods to (1) reduce platelet activation during collection, component preparation, and storage; (2) reduce platelet metabolism,[46] thereby decreasing the rates of in-storage glucose consumption and lactate production; and (3) ensure that glucose is not exhausted in the storage medium prior to component outdate.[47]

Most alternatives studied or currently under development are composed of buffered salt solutions containing various additives such as acetate and gluconate.[47–49] Acetate, like glucose and fatty acids, acts as a substrate for platelet metabolism and provides the highly desirable side effect of bicarbonate production during its consumption, which helps buffer pH. Glucose-free crystalloid solutions do not appear to maintain concentrate pH and are associated with reduced in vivo recovery after 5 days of storage.[50] Other investigators have suggested placing various additives in the platelet storage bag that inhibit platelet and coagulation factor activation such as prostaglandin E_1, theophylline, aprotinin, and hirudin.[51–53] Although platelet shelf life can possibly be extended with these additives, the potential for harmful side effects, especially in infants and pregnant women, has slowed their commercial development. Moreover, these solutions could not be deployed to extend the shelf life of stored platelets without the availability of suitably robust methods to detect and limit bacterial contamination.

Storage Temperature

Current Storage Standards

Liquid platelet concentrates were originally stored at 4°C until the late 1960s when it was discovered that products stored at room temperature had longer in vivo survival and greater hemostatic efficacy than those stored at the colder temperature.[54–56] In fact, the shelf life of liquid platelets stored at 22°C was extended from 5 to 7 days in 1984 by the U.S. Food and Drug Administration (FDA) owing to a combination of improved plastic storage containers and increased storage temperature. Within 2 years, however, a marked increased in the incidence of platelet transfusion–related bacterial sepsis prompted the FDA to reduce the maximum storage period back to its current 5-day limit.

The optimal liquid platelet storage temperature appears to be 20°C to 24°C with continuous gentle agitation. While colder storage temperatures demonstrably slow bacterial growth, platelets stored in the cold become activated and lose their normal discoid shape.[57] Development of spherical morphology on exposure to cold has long been recognized as evidence of irreversible physical damage.[58] Changes in platelet morphology have been observed even following short-term (24 hours) exposure to temperatures below 20°C, as may occur during platelet transport. The mechanism for these changes may be related to the release of calcium ions from platelet dense bodies or to influx of calcium across the platelet membrane, resulting in actin filament assembly and, subsequently, platelet activation.[59,60] Chilled platelets have recently been shown to undergo rapid clearing from the circulation by hepatic macrophages. This clearance is mediated by the $\alpha_M\beta_2$ integrin (a complement receptor type 3/Mac-1) that binds to clustered GP1b receptors on the surface of chilled platelets, resulting in rapid platelet phagocytosis.[61] Binding occurs through a lectin-mediated interaction with exposed β-*N*-acetylglucosamine (β-GlcNAc) residues on the GP1b complex. Enzymatic galactosylation of exposed β-GlcNAc residues, however, has been shown to inhibit $\alpha_M\beta_2$ binding, resulting in normalization of chilled platelet intravascular circulation time.[62]

Investigative Strategies for Extended Cold Storage

If changes in the platelet cytoskeleton can be prevented, long-term storage of liquid platelets could become feasible. Platelets treated with cytochalasin B, an inhibitor of

new actin filament assembly, do not develop pseudopods or undergo spreading when cooled to 4° C.[63] Human platelets stored for 21 days at 4° C with EGTA-AM, a cytoplasmic Ca^{2+} chelator, and cytochalasin B remain responsive to ADP and thrombin in the presence of exogenous calcium. Other strategies have been developed to allow for preservation of platelet morphology and function during cold storage. These include trehalose, a disaccharide used during freeze-drying, and the antifreeze glycoproteins (AFGPs). The latter proteins are isolated from fish that have adapted to survive in the cold temperatures found in the polar regions. AFGPs reduce platelet activation that occurs when human platelets are stored in the cold.[57] Despite these observations, the future role of cold-stored platelets in clinical transfusion practice remains unclear.

Cryopreserved Platelets

Similarly, the use of cryopreserved platelets remains limited in clinical practice. Platelets frozen in a cryoprotectant solution of 5% to 6% dimethyl sulfoxide (DMSO) can be stored for a period of years at −80° C. Post-thaw ex vivo recovery has been reported to be 75%, with an in vivo 1-hour recovery in normal volunteers of 33% and 8-day survival.[64] The clinical utility of frozen platelets, however, is diminished by the lack of trained personnel and facilities at most hospitals for their preparation, storage, and reconstitution.[65] Thus, widespread adoption of the use of cryopreserved platelets currently appears unlikely. Some investigators, however, support their use in specialized circumstances, such as for autologous or allogeneic donation for subsequent transfusions to manage treatment-related thrombocytopenia in patients with malignancies.[66]

Platelet Storage Containers

Development of Gas-Permeable Plastic Storage Bags

The critical importance of oxygen-permeable containers was recognized shortly after the development of plastic bags for the storage of platelet concentrates. It was appreciated that if oxygen supply to the platelet was inadequate, then metabolism would shift from primarily aerobic to the anaerobic glycolytic pathway. This pathway produces high concentrations of lactic acid, which reacts with the bicarbonate buffer in the plasma. When bicarbonate is exhausted, at levels of 20 to 25 mmol/L of lactic acid, there is a rapid reduction in pH with a resultant loss of platelet viability. Adequate entrance of oxygen into the storage bag, conversely, allows platelets to maintain energy metabolism through mitochondrial oxidative phosphorylation.

Plastic bags originally developed to store platelet concentrates were composed of polyvinyl chloride (PVC) containing a di-2-ethylhexyl phthalate (DEHP) plasticizer and did not permit storage of platelets beyond 3 days. The walls of such plastic bags failed to allow sufficient CO_2 and oxygen exchange for platelets to sustain aerobic metabolism. After 3 days of storage, anaerobic metabolism would produce enough lactic acid that the pH of concentrates routinely fell below 6.0. These changes markedly reduced in vivo platelet recovery and survival.[33,67,68]

Storing platelets in gas-permeable storage bags that permitted the influx of oxygen and the efflux of carbon dioxide was found to ameliorate these untoward effects. It was later discovered that platelet concentrate pH can be adequately maintained for 5 days by storing 50 to 65 mL of PCS in more gas-permeable blood bags made of either PVC with a trimellitate, non-DEHP plasticizer such as TOTM (Fenwal PL1240 or Cutter CLX),[69] or blow-molded polyolefin (Fenwal PL732).[70] Other second-generation platelet storage bags were composed of thin-film PVC with a 2-DEHP plasticizer (XT-612; Terumo), and PVC with a citrate-based non-DEHP plasticizer (butyryl-tri-hexyl citrate [BTHC]; Fenwal PL2209). The latter compound, PL-2209, allows storage of $5–7 \times 10^{11}$ platelets/bag in 400 mL of plasma for 5 days at 20° C to 24° C with acceptable in vitro and in vivo storage characteristics.[71]

Plasticizers and Potential Toxicity

Despite their use since the 1950s, there remain concerns regarding the potential toxicity of storage bags composed of PVC plastic with a DEHP plasticizer, which readily leaches into the blood product.[72–74] These concerns, which include the possible carcinogenicity of DEHP and its monoethylhexyl phthalate (MEHP) metabolite, have led to the development of various alternative plasticizers used in blood storage containers.[75,76] Studies have suggested that transfusing platelets stored in BTHC containing bags, for example, is safe.[77] BTHC leaches into plasma at a level 60% to 70% lower than does DEHP. Moreover, BTHC differs from the phthalate plasticizer in that BTHC is metabolized to physiologic compounds like citric acid, butyric acid, and hexanol. Extensive toxicology testing has shown that BTHC has a very low level of toxicity and that the plasticizer and its degradation products are rapidly eliminated from the body by pulmonary, fecal, and urinary routes. Although gas permeability of the material is slightly less than that of PL-732 plastic, there is sufficient transmission of oxygen into, and carbon dioxide out of, the container to ensure aerobic oxidative metabolism and maintenance of an acceptable pH.

Platelet Storage Agitation

In the late 1970s, it was found that platelets stored with gentle agitation maintained better morphology and in vitro functionality than platelets stored undisturbed.[78] Thus, platelets are now stored with continuous gentle agitation. Rotators are available in a face-over-face (circular) angle of rotation or in a flatbed configuration.[37] However, not all agitators are appropriate to store platelets collected in certain plastic containers. For example, platelets stored in PL732 blow-molded, polyolefin bags using 6-rpm elliptical rotators showed decreased post-transfusion recovery and survival.[70] These findings were thought to be related to platelet–plastic storage bag interactions at various shear stresses created with agitation. Platelet storage using any available storage bag–rotator combination is associated with increasing levels of CD62P over time and progressive release of β-thromboglobulin from α-granules. Agitation is also associated with discharge of cytosolic lactate dehydrogenase (LDH), suggesting that some degree of platelet lysis occurs during agitation.[79]

Apheresis-Derived Platelets

Development of Apheresis Collection Technologies

The development of automated instruments for platelet collection was, in part, motivated by the need to collect large

numbers of platelets from a single donor.[80] It was clear during the earliest periods of platelet transfusion therapy that some patients did not demonstrate expected increases in platelet counts following transfusion. However, these patients often had better responses when transfused with platelets collected from HLA-identical siblings.[81] Later, platelets collected from unrelated donors that were HLA-identical to the recipient were also found of use in unrelated platelet-refractory patients.[82]

Advances in apheresis technology have resulted in improved collection efficiencies for various apheresis machines.[83,84] These instruments are highly automated and can also be used to collect granulocytes, red blood cells, and plasma.[85] Apheresis machines routinely collect 5 to 7×10^{11} platelets from a single donor. In fact, many centers are collecting two or three individual units from a single donor collection, each unit containing more than the 3×10^{11} platelets which many standards require for a single-donor apheresis unit.[86] The platelets are collected in larger storage containers that allow adequate transport of oxygen and maintenance of pH. Inability to provide adequate transport of oxygen into the storage bag and, to a lesser degree, adequate transport of carbon dioxide out, limits the number of platelets that can be stored. Currently available citrate-based plasticizer bags can store up to 7×10^{11} platelets in a bag. Like WB-Plts, apheresis products must also be stored at 20°C to 24°C with continuous gentle agitation. Generally, apheresis platelets are collected in ACD-A solutions rather than the standard whole blood anticoagulants CPD, CP2D, or CPDA-1. AD-Plts show in vitro characteristics comparable to, or better than, those of random-donor platelets prepared from whole blood donation.

Apheresis In-Process Leukoreduction

Refinements in apheresis technology now permit in-process leukoreduction capable of achieving a 3 to 4 log-order reduction in the number of residual leukocytes in an AD-Plt unit. This allows collection of highly enriched platelet products with white blood cell contamination levels low enough to allow the unit to be designated as "leukoreduced." This form of "process leukoreduction" appears to provide several direct benefits that include[1] minimizing the levels of various cytokines such as TNFα, which have been implicated in febrile transfusion reactions[87]; (2) reducing the risk of transfusion-related CMV transmission due to virally infected passenger leukocytes[88]; and (3) reducing the risk of platelet refractoriness and HLA alloimmunization.[89] An additional and oft-cited additional benefit is that of "limiting donor exposure." Most transfusion specialists do not believe that it is necessary to administer these products through leukoreduction filters to further reduce the number of white cells.

Autologous Platelet Donation

Several groups have explored the feasibility of autologous platelet donation. Platelets stored in the liquid phase at room temperature currently have a shelf life of only 5 days, making autologous donation impractical. However, platelets collected by apheresis and frozen preserved in DMSO can be stored at −80°C for long periods of time.[90] They are then thawed, washed, and resuspended in autologous plasma or other solutions before transfusion. Platelets prepared by this technique, however, do undergo a number of structural and metabolic changes that decrease their recovery and survival, as compared with liquid-stored platelet concentrates.[91] Furthermore, most patients cannot donate sufficient platelet units to support their needs, for instance, during a course of induction chemotherapy. It is possible, however, to store significant numbers of frozen autologous platelets for patients who are refractory to platelet transfusion, provided the blood bank is technically capable of preparing and storing these specialized products.[92]

Transfusion Practices: Use of Whole Blood–Derived versus Apheresis Platelets

The transfusion practice at a given hospital or medical institution with respect to the use of AD-Plts platelets versus WB-Plts is often dependent on local issues, such as economics, budgetary constraints, and the ability of the local blood supplier to provide these products. Blood collection centers vary in their ability to provide AD-Plts owing to the size and makeup of their donor population, as well as the extent of local facilities and expertise to support apheresis collection. Although an estimated 70% of all platelet transfusions in the United States are leukoreduced apheresis platelet units, blood collection agencies are still unable to meet 100% of the demand with AD-Plts, and the use of WB-Plts remains commonplace in many regions of the country. It is also worthy of note that while platelet collection by apheresis is well tolerated by most donors, hemodynamic instability and adverse reactions related to citrate toxicity (hypocalcemia) can occur.[93] Additionally, recent toxicologic studies investigating intravenous exposure to DEHP in a volunteer apheresis platelet donor demonstrated that exposure to the plasticizer and its metabolites could exceed the U.S. Environmental Protection Agency's Reference Dose (RfD) of 20 μg/kg/day for DEHP on the day of donation.[94] The authors recommended adoption of measures to protect donors from DEHP exposure, particularly potentially at-risk populations such as women in their reproductive years.

Volume-Reduced Platelets

Clinical Indications for Volume Reduction

Platelets prepared from whole blood collections are stored in donor plasma, which serves as a buffering agent. WB-Plts are typically suspended in 40 to 60 mL of plasma to maintain product pH greater than 6.0 for the duration of storage.[95] Volume-reducing platelets for neonates is not usually necessary, because adequate platelet increments are achieved by transfusing small volumes of platelets; 10 mL/kg is a standard dose for neonates.[96] There are specific clinical situations, however, in which volume-reduced platelets are considered. For example, transfusing plasma-incompatible platelets, a reasonably common adult transfusion practice, is of more potential harm to infants with smaller red cell volumes. The most dangerous scenario is when a group A infant is transfused with AD-Plts from a group O donor who carries high-titer anti-A.[96] For this reason, blood services that provide mainly AD-Plts may titer group O products before they are transfused to group A recipients. If ABO-compatible platelets are not available, plasma can be removed from the platelets by centrifugation and replaced with saline or albumin. Plasma removal is also considered when an antibody present in donor plasma is

directed against an antigen present on a neonatal blood cell. This situation arises when an HPA-1a negative mother is the only source of antigen-negative platelets for her newborn with neonatal alloimmune thrombocytopenia due to anti-HPA-1a. Volume-reduced platelets may also be warranted when circulatory overload is a major concern, as part of an overall restriction of intravenous fluids.

Platelet Effects of Volume Reduction

Recentrifugation of platelets stored for up to 5 days at 1500 × *g* for 7 minutes, 2000 × *g* for 10 minutes, or 5000 × *g* for 6 minutes, followed by resuspension in 10 mL of plasma after a 1-hour rest period, results in a loss of 5% to 20% of the platelets.[97] At the latter two centrifuge speeds, in vivo survival of the platelets that tolerate centrifugation/resuspension appeared normal in healthy volunteers. Platelet loss is less than 15% after a shorter 20-minute rest period, when platelets are spun at lower speeds but for longer times (e.g., 580 × *g* for 20 minutes).[98] Platelets stored for 1 or 5 days either on a flatbed or an end-over-end tumbler agitator and then volume-reduced showed no adverse effects on in vitro function as assessed by morphology, response to hypotonic stress, aggregation, platelet factor 3 activity, pH, and discharge of lactate dehydrogenase (LDH). Acceptable platelet increments can also be obtained in critically ill thrombocytopenic neonates transfused with volume-reduced AD- or WB-Plts. The use of the softer spin technique to produce volume-reduced PCs has the advantage of more rapid availability of products. Recent studies have confirmed the adequacy of recentrifuged, volume-reduced platelets, although data from one study demonstrated a higher level of spontaneous activation (43.2%, control 33.8%) and impaired ADP-induced but not collagen-induced aggregability of treated AD-Plts versus control platelets.[99]

Use of Syringe Storage for Neonatal Transfusion

Neonates usually require small-volume transfusions; therefore, blood components are often dispensed or transfused with a syringe. For platelets to maintain an acceptable pH, it is imperative that the storage container allow sufficient gas exchange. Platelet concentrates stored for up to 5 days and then maintained in gas-impermeable polypropylene syringes for 6 hours showed increases in consumption of glucose and production of lactic acid.[100] The resultant decline in pH was associated with a switch from aerobic to anaerobic metabolism. Similar results were observed when platelets were stored in syringes for 6 hours at 37° C. The pH in all these situations, however, never fell below 6.5, which is within the accepted range for platelets stored in gas-permeable blood bags. Volume-reduced platelets produced by the soft-spin technique described above and stored in syringes for 6 hours at room temperature or 37° C were also evaluated.[101] Higher temperature storage produced the greatest and most rapid decline in pH. Other in vitro parameters of platelet function, such as morphology score, response to hypotonic stress, and LDH discharge were not adversely affected under the conditions studied. Therefore, it appears that PCs, either standard or volume-reduced, that are dispensed to neonatal nurseries in syringes for transfusion within 4 to 6 hours maintain acceptable in vitro platelet function.

STANDARDS AND QUALITY CONTROL OF PLATELET CONCENTRATE MANUFACTURE

Standards for Platelet Concentrates

In many respects, the standards for platelet products have evolved in parallel with advances in processing and storage conditions that allow longer storage of viable platelets. Quality assurance (QA) programs have been developed to monitor the composition and viability of platelets.[102] These procedures are designed to minimize the variability in end products—variability that can preclude determining the efficacy of platelet products. Standards for monitoring the quality of platelet products vary across countries and are specific for the preparation technique. Most standards require that platelet product testing include platelet numbers, pH, white cell numbers for leukoreduced products, and product volume (Table 23–1).[103] In the United States, WB-Plts must contain a minimum of 5.5×10^{10} platelets per bag; AD-Plts must contain at least 3.0×10^{11} platelets per bag. Platelet counts are commonly determined using automated hematology analyzers whose precision and accuracy is acceptable for this purpose. Flow cytometric methods have also been developed that allow for precise platelet enumeration.

Table 23–1 **Standards for Platelet Products**

	United States*		Europe†	
	Whole-Blood Derived	**Apheresis Derived**	**Whole-Blood Derived**	**Apheresis Derived**
Platelets ($\times 10^{10}$)	≥5.5	≥30	Varies#	Varies#
Volume (mL)	Not specified	Not specified	Not specified"	Not specified"
White cells ($\times 10^{6}$) to label leukoreduced	<0.83‡	<5.0‡	<1.0§	<1.0§
pH	>6.2	>6.2	6.4–7.4	6.4–7.4

"Volume must maintain product within specified pH for duration of storage.
#Platelet number within limits that comply with validated preparation and preservation conditions.

These utilize fluorescent dyes and monoclonal antibodies conjugated to fluorochromes.[104] These techniques, which require a flow cytometer or other instrument capable of detecting fluorescence, are not routinely used in platelet quality monitoring.

The volume of suspending plasma is not specified; however, the amount must be sufficient to maintain a pH greater than 6.0 for the duration of storage. Prior to pretransfusion release of a platelet concentrate, some investigators advocate inspecting the unit for the presence of the "swirling phenomenon" in which normal discoid platelets exposed to light and rotated display a characteristic appearance.[105] Presence of swirling, which suggests grossly normal platelet morphology, may correlate with acceptable pH values and adequate in vivo viability.[106,107] There is no requirement, however, to check for swirling prior to issue of platelet components. Finally, temperature control charts should document that platelets are stored at 20°C to 24°C in an uninterrupted manner.

Standards for Leukocyte Reduced Platelets

Allowable Levels of White Cell Contamination

Platelets may be designated as "PLATELETS LEUKOCYTES REDUCED" although the criterion for this designation differs between the United States and Europe. Current standards in the E.U. mandate that leukoreduced platelet units contain $<1 \times 10^6$ white cells per unit, whereas U.S. FDA standards allow $<5 \times 10^6$ white cells per unit, provided that a minimum of 85% of the original product be retained if leukoreduction filters are employed.

Methods for Determination of Residual White Cell Counts

Most blood collection centers continue to use manual methods to determine residual white blood cell counts for quality control (QC) purposes. Automated hematology analyzers that are commonly used in clinical laboratories utilize techniques based on the principles of impedance or light-scattering properties of cells suspended in a liquid medium. These techniques, however, lack the requisite precision and accuracy at very low residual white blood cell numbers that are commonly encountered in leukoreduced blood products—generally on the order of 5 cells/μL—and thus cannot be used for QC purposes. At present, residual white blood cell numbers are most commonly performed by manual chamber techniques. Larger volume (50 μL) Nageotte type hemacytometers using Turk's or Plaxan's staining solutions are typically employed.[108,109] The variability of chamber counts, however, is considerable,[110] which has prompted development of alternative techniques. These include methods based on flow cytometry, microvolume fluorimetry, and quantitative polymerase chain reaction.[111–114] Most flow cytometric methods developed to count residual leukocytes use dyes that stain nuclear components (propidium iodide) or leukocyte-specific antibodies (CD45) conjugated to a fluorochrome.

Quality Control Sampling Requirements

Current methods of leukoreduction (LR), when properly performed, consistently provide products that fulfill standards for white blood cell removal.[115] However, a proportion of products must be sampled within a QC program to document adequate LR.[116] Only a small number of the platelet products produced are actually sampled because it is not currently feasible to test all products. Typically, from 4 to 10 products per month, or 1% of all products collected, are tested for WC numbers. Concerns have been expressed that such sampling numbers and sampling frequencies are inadequate.[117] Ideally, the QC program should include a formal technique for statistical monitoring that is performed on a continuous basis. These steps could maximize the likelihood of detecting process failures. However, most facilities continue to test platelet products at weekly or monthly intervals.

Standards for Detection of Bacterial Contamination of Platelets

Current AABB Standards to Limit and Detect Bacterial Contamination

In the United States, inspecting and accrediting agencies such as the American Association of Blood Banks (AABB) have recently instituted standards that must be followed to limit and detect bacterial contamination of all platelet units. The 22nd edition of the AABB *Standards for Blood Banks and Transfusion Services* mandates that "blood bank or transfusion service shall have methods to limit and detect bacterial contamination of all platelet components" and that "the venipuncture site shall be prepared so as to minimize the risk of bacterial contamination. Green soap shall not be used."[118] Although originally scheduled for implementation by November 1, 2003, logistical concerns led to a revised implementation date of March 1, 2004, for the new standard. Additional AABB Association Bulletins were subsequently published to provide guidance and clarification regarding specifics of implementation. In addition, the College of American Pathologists (CAP) now includes testing for bacterial detection of platelets as part of its Transfusion Medicine Checklist as a Phase I requirement for laboratory accreditation.[119]

The requirements for additional measures to detect and limit bacterial contamination were prompted by growing concerns over transfusion-related bacterial sepsis and fatalities, particularly associated with platelet transfusions. In order to ensure appropriate in vivo function and survival, platelets are stored at 20°C to 24°C with gentle agitation in oxygen-permeable bags as previously described. These storage conditions render platelets particularly susceptible to bacterial contamination. Of the estimated 9 million platelet units transfused in the United States annually,[120] approximately 1:1000 to 1:3000 are bacterially contaminated—a figure that has remained remarkably consistent over numerous studies.[121–124]

Transfusion-Related Deaths Due to Bacterial Contamination

FDA statistics on transfusion-related fatalities underscore the seriousness of microbial contamination of blood products: 46 (17%) of the 277 reported transfusion-related deaths during the period 1990 to 1998 were due to bacterial sepsis.[125] Rates of serious, potentially life-threatening sepsis due to bacterially contaminated platelets have been estimated at 1:50,000 to 1:100,000 transfused units; rates of immediate fatality are estimated at 1:500,000.[120,126] Data on adverse outcomes of transfusion, however, remain limited,

and these estimates may be low; prospective studies from the Johns Hopkins University Hospital[127] and University Hospital of Cleveland[128] reported the risk of fatality due to bacterially contaminated AD-Plts at 1:17,000 and 1:48,000, respectively.

Historically, rates of platelet transfusion-related sepsis have been closely tied to duration of product storage. Nearly all the platelet-transfusion related fatalities reported to the FDA in the late 1990s were with units that were 4 or 5 days old.[125] Recognition of this phenomenon gained widespread attention in the mid-1980s, as improvements in platelet storage containers led to an extension of the maximal platelet storage time from 3 to 5 days in 1982, and from 5 to 7 days the following year. Concurrent with longer platelet storage was a marked increase in the number of FDA-reported deaths due to bacterially contaminated platelets: four cases were reported in 1983 alone, compared with only a single case reported in the period from 1976 to 1979.[129] In response, the FDA reduced the allowable platelet storage duration back to 5 days in 1986, resulting in a decline in the rate of reported cases of bacterial sepsis due to contaminated products.

Through this period and into the mid-1990s, interest in the issue of bacterial contamination was largely eclipsed by greater concerns for viral transfusion-transmitted disease (TTD) risks, particularly human immunodeficiency virus (HIV) transmission. Improvements in donor screening and viral detection methods, particularly with the advent of nucleic acid amplification technology (NAT) based methods, led to a dramatic reduction in the risk of viral TTDs.[130] With reductions in the risk of HIV, hepatitis B (HBV), and hepatitis C (HCV) infection, attention once again turned to the issue of bacterial contamination, which had seen no significant reduction in rates in over a decade. Three FDA-sponsored workshops on bacterial contamination of platelets were convened to review the scope of the problem and discuss possible interventions.[125,131,132] Supporting the need for measures to curb rates of bacterial contamination were data from numerous national transfusion surveillance programs, including the BaCon Study (U.S.),[133] Serious Hazards of Transfusion (SHOT) study (U.K.),[134] and the French Haemovigilance System.[135]

Spectrum and Sources of Bacterial Contaminants

Gram-Positive versus Gram-Negative Bacterial Contamination

A broad spectrum of contaminants have been isolated in cases of platelet transfusion-associated sepsis including *Staphylococcus* spp., *Streptococcus* spp., *Bacillus* spp., *Escherichia coli*, *Salmonella* spp., *Serratia* spp., *Enterobacter* spp., and other organisms.[133,134] In a review of transfusion-transmitted bacterial infections, Wagner found that over half (56%) of all reported isolates in cases of bacterial contamination of platelets were gram-positive organisms, the majority of which were aerobes. He also noted differential representation of bacterial species in cases of clinical sepsis versus sepsis-related deaths. *Staphylococcus epidermidis* was more commonly encountered in cases of clinical sepsis than in septic fatalities, whereas *Klebsiella* spp. were only rarely encountered in cases of clinical sepsis but represented 17.3% of cases of septic fatalities. Overall, approximately 60% of sepsis-related deaths were due to gram-negative organisms. Based heavily on data from work done by Brecher and others,[136] a list of organisms required for bacterial contamination detection system clearance by the FDA was drafted. The list includes representatives of the most commonly isolated gram-positive and -negative organisms, aerobes and anaerobes, and the fungus *Candida albicans*.

Sources of Bacterial Contamination

Investigators in the aforementioned studies frequently noted that sources of bacterial contamination often could not be definitively identified, although considerable evidence pointed to three primary sources[137]:

1. Donor skin flora
2. Donor bacteremia (asymptomatic) at the time of collection
3. Contamination during product manufacture

Bacterial contamination by donor skin flora may occur as a result of several mechanisms including inadequate donor arm-skin disinfection,[138] scarring at the phlebotomy site with resultant harboring of bacteria,[139] and contamination of collections by phlebotomy needle-associated skin cores or flaps.[140] Asymptomatic donor bacteremia at the time of blood donation is a well-recognized phenomenon and has occurred in the setting of chronic enterocolitis infection, chronic gut infection, chronic osteomyelitis, and following medical or dental procedures.[141,142] Contaminated apheresis solutions, water baths, etc., have also been implicated as portals of bacterial contamination.[125]

Methods to Limit Bacterial Contamination of Platelets

Donor Phlebotomy Site Disinfection and Initial Collection Diversion

AABB standards mandate methods to both *limit* and *detect* bacterial contamination of platelet components. Although considerable recent effort has been devoted to developing more sensitive methods of bacterial detection, improvements in prevention of bacterial contamination have also been reported. Improved donor phlebotomy site disinfection and methods to divert an initial aliquot of blood have both been associated with decreased rates of skin flora contamination of blood products. McDonald and colleagues reported a 57% rate of reduction in bacterial contamination rates using a two-stage procedure with 70% isopropyl alcohol followed by 2% tincture of iodine, as compared with a one-stage process using 70% isopropyl alcohol and 0.5% chlorhexidine wipe system.[143] He also reported a 47% reduction in contamination rate using a collection bag system that allowed diversion of the first 20 mL of collection into a sampling pouch. When combined, improved donor arm preparation with diversion resulted in an overall 77% reduction in contamination. The results of these interventions are consistent with decreased bacterial contamination rates reported by other investigators.[138,144,145]

Methods to Detect Bacterial Contamination of Platelets

Numerous methods for detection of bacterial contamination of platelets are both in current clinical practice and in

ongoing development. These vary widely with respect to analytical sensitivity, procedural complexity, turn-around time, cost, and time-to-detection characteristics. Comprehensive reviews of current and investigational technologies have recently been published.[126,137]

Culture-Based and Nonculture "Surrogate" Detection Methods

Current methodologies can be broadly divided into culture-based and nonculture ("surrogate") methods. In bacteriology, culture remains the "gold standard" for sterility testing,[146] and automated bacterial culture systems have been extensively investigated. Surrogate methods such as visual inspection for swirling, Gram staining, pH, and glucose analysis, while less sensitive, are generally faster and less costly. At present, culture-based methods tend to be utilized by blood collection facilities near the time of collection, whereas surrogate methods are more commonly employed in prerelease testing by hospital-based transfusion services.

Surrogate Bacterial Detection Methods: Visual Swirl, Reagent Strip pH and Glucose Semiquantification, and Direct Visualization of Organisms

Surrogate methods for detection of bacterial contamination are based on changes in platelet unit pH, glucose concentration, and platelet morphology due to activation that occurs in response to increasing levels of microbial contamination. In general, these methods lack analytical sensitivity and can only reliably detect heavily contaminated units. Presently, the AABB recommends use of surrogate methods only for prerelease testing owing to their poor analytical performance characteristics.[147,148]

Visual inspection for "swirling" can easily be performed by trained personnel. Loss of swirl occurs when pH drops sufficiently to inhibit platelet metabolism: the normally discoid platelets then become spherical. This shape change is associated with loss of visual "swirl." Although use of this method is simple, rapid, and noninvasive, it is highly subjective, difficult to validate, and has a detection sensitivity of $\geq 10^7$ colony-forming units (CFU)/mL.[148]

Multireagent strips ("urine dipsticks") for pH and glucose have shown similar levels of sensitivity ($>10^7$ CFU/mL), although some authors have reported greater sensitivities.[149] Validation studies for pH and glucose concentration are collection bag/preservative solution specific and have been reported for the Baxter PL732 CPD bag and the Medsep CLX CP2D bags. A pH of <7.0 and glucose of <250 mg/dL in the Baxter PL732 bags or ≤500 mg/dL for the Medsep CLX bags was predictive of bacterial contamination.[147]

Direct visualization of microorganisms using staining methods may also be employed. These generally utilize Gram's stain, Wright's stain, or acridine orange and have reported sensitivities of approximately 10^5 CFU/mL[106] for Wright's and Gram's stains and 10^4 CFU/mL for acridine orange.[126,147] Successful use of staining methods to interdict contaminated platelet units has been previously reported.[121]

Culture-Based Bacterial Detection Methods

Although culture remains the gold standard for bacterial detection and identification, its sensitivity in detecting bacterial contamination of blood products is affected by numerous factors including the growth characteristics of the contaminating organism, timing of specimen procurement, specimen volume, and degree of initial bacterial contamination. Numerous studies of culture-based detection systems have been performed. These have demonstrated that the timing of specimen collection is critically important to test sensitivity: cultures obtained on the day of collection invariably fail to demonstrate bacterially contaminated units that could develop clinically significant overgrowth during storage.[150] Because of the small sample volume normally obtained, reliable detection requires time for the organisms to proliferate to levels at which sampling would include adequate numbers of the organism. Currently, most detection system manufacturers recommend at least a 24-hour incubation period prior to sampling.

Current FDA-Approved Culture-Based Detection Systems

Of the various automated or semiautomated culture systems in use in clinical bacteriology laboratories, only two are presently FDA approved for QC testing for bacterial detection of platelet products in the United States: BacT/ALERT (bioMérieux, Durham, N.C.) and the Pall Enhanced Bacterial Detection System (eBDS) (Pall Corp., East Hills, N.Y.). The BacT/ALERT system uses broth bottles with colorimetric sensors that detect changes in CO_2 levels that occur with bacterial proliferation. Several investigators have validated its sensitivity and specificity in the detection of a wide variety of organisms.[151–154] The system reliably detects contamination levels of 10 CFU/mL or less in 12 to 26 hours, although slower growing organisms such as *Propionibacterium acnes* may take longer to detect.

The Pall eBDS system provides testing in an essentially closed system in which the inoculation receptacle is provided as a satellite bag connected to the main platelet component bag. A 5- to 6-mL sample is expressed from the storage bag into the inoculation bag and allowed to incubate. Following incubation, oxygen tension in the head space of the bag is measured: a drop in O_2 tension indicates bacterial contamination. Independent validation studies of the eBDS system have reported analytical sensitivities for 10 common bacterial contaminants of 96.5% at 24 hours and 100% at 30 hours.[155]

Laboratory Detection of Bacterial Contamination versus Clinical Outcomes

Despite promising early validation studies, clinical studies of culture-based as well as surrogate method bacterial detection strategies have revealed occasional discordance between laboratory findings and clinical outcomes. In 2005, te Boekhorst and coworkers reported their 2-year experience with universal bacterial screening of all pooled platelet concentrates using the BacT/ALERT system.[156] Of the 28,104 products tested, 203 generated a positive signal (0.72%) of which 184/203 were confirmed true positive (0.65%). Of these bacterially contaminated units, 113/184 had been transfused prior to positive screening, and none were associated with clinically detectable transfusion reaction. Conversely, two patients developed severe, life-threatening sepsis with *Bacillus cereus* that was cultured from both the patient and the platelet bag at the time of the reaction. In both cases, 7-day screening cultures were negative. Similar reports of negative screening results associated with severe or fatal septic transfusion reactions from contaminated platelet units have been reported.[120] This has led some investigators to call for stricter requirements for bacterial testing of platelet units.[157]

Extended Platelet Storage

With the institution of the new standards to both *limit* and *detect* bacterial contamination of platelet products, consideration is once again being given to increasing the maximum storage time of platelets to 7 days. Some have argued that the additional cost burden of mandatory culturing could be mitigated in part by the more favorable inventory situation that extended platelet storage would provide.[158] At present, only Gambro BCT AD-Plt technology has been cleared by the FDA for 7-day platelet storage.[159] This system requires use of an approved release test for bacterial contamination screening, as described in the manufacturer's instructions for use (IFU). Owing to the low incidence of bacterial contamination of platelet units, FDA approval has been coupled with mandatory postmarket surveillance study to estimate the performance of the bioMérieux BacT/ALERT Microbial System when used as a release test with Gambro AD-Plts.

CHANGES IN PLATELETS WITH STORAGE

Platelet-Storage Defect

The platelet-storage defect (PSD), or platelet-storage lesion (PSL), encompasses all untoward effects on platelet morphology, structure, and function with storage. These changes begin at the time of blood collection and component preparation and continuously progress during storage. The mechanisms responsible for the PSD are not fully understood but are clearly multifactorial. Development of the PSL is in general related to collection technique, storage conditions, and postcollection manipulation.[160] For example, centrifugation can affect platelet function by exposing platelets to shear stress conditions. Shear stresses not only produce a discharge of cytosolic LDH but also stimulate the platelet release reaction.[79] Release of β-thromboglobulin into the suspending plasma and appearance of P-selectin (CD62P, GMP-140) on the platelet membrane surface following platelet preparation are both evidence of platelet granule release.[161,162]

During storage, the metabolic activity of platelets and residual leukocytes continues to consume nutrients and produce harmful metabolic products. Activated clotting factors, cellular debris, and proteolytic enzymes found in the suspending plasma can adversely affect platelets. Many structural changes to the platelet cytoskeleton and surface membrane antigens that occur during storage also appear related to poorer in vivo post-transfusion recovery and survival.[163] A vast array of in vitro tests have been used to follow changes in platelets with processing and storage (Table 23–2). In general, only platelet numbers, concentrate volumes, pH at 5 days, and leukocyte content are routinely measured in transfusion practice. The remaining assays, primarily relegated to research settings, correlate to varying degrees with in vivo platelet survival. Techniques used to study in vivo platelet survival—mainly, radiolabeling or biotinylation of platelets prior to transfusion—are not commonly performed and have their own limitations.[164,165] Many of these supplemental assays cannot be applied to large-scale platelet production. Unfortunately, there is no single in vitro assay that can accurately predict in vivo recovery and survival of transfused platelets.

Table 23–2 **Analytic Methods for Characterizing Platelets and Quantifying the Platelet Storage Defect**

Type of Analysis	Method
Routine studies	Platelet number Concentrate volume pH Visual inspection, swirl Leukocyte content
Morphology and shape changes	Qualitative swirling Morphology score Mean platelet volume Osmotic recovery Extent of shape change
Metabolic activity	pH, pO_2, pCO_2, HCO_3 changes Lactate production Glucose consumption Intracellular calcium ATP/ADP ratio
Platelet aggregation	Spontaneous aggregation Response to dual agonists
Platelet activation	CD62 P-selectin expression Annexin V binding
Platelet lysis	Supernatant LDH content Lysate vWF:Ag levels
Miscellaneous	Cytokine levels Activated complement Bacterial growth
In vivo assays	Corrected count increment Radiolabeled survival Biotin-labeled survival

Platelet Activation during Preparation and Storage

A variety of markers have been employed to examine the platelet activation that occurs during the storage of platelet concentrates. These include proteins associated with the α-granule, such as β-thromboglobulin, platelet factor 4, and P-selectin; dense granule proteins such as serotonin; cytosolic enzymes such as LDH; and membrane ligands including GPIb and GPIIb/IIIa.[166,167] There is little evidence that the degree of platelet activation associated with routine platelet preparation and storage adversely affects the ability of transfused platelets to circulate, correct the bleeding time, produce acceptable corrected count increments, and arrest bleeding. In fact, activated platelets have been shown to continue to circulate and function in a nonhuman primate model of platelet transfusion.[168] However, it is likely that platelet activation attributed to the preparation and storage of platelets is partially responsible for their deterioration, as assessed by certain in vivo tests of platelet function.[169]

Platelet Activation and Expression of P-Selectin

P-selectin (CD62P, previously known as GMP-140 or PADGEM) is an important adhesive protein involved in platelet/leukocyte/endothelial interactions. Its functions are related to leukocyte attachment, rolling, and extravasation and the regulation of leukocyte cytokine synthesis.[170] This α-granule membrane protein is sequestered on the internal membrane of the α-granule in resting platelets. Platelet activation through most mechanisms results in fusion of

the α-granule with the platelet membrane. P-selectin then becomes expressed on the outer surface of the platelet membrane.[171] Thus, the number of platelets that have undergone α-granule release can be estimated by measuring the total surface content of P-selectin.

Several investigators have used monoclonal antibodies directed against P-selectin to study platelet activation during PCS preparation and storage.[172] Platelet preparation by the PRP technique can result in P-selectin expression by approximately 20% of platelets. Platelet activation is in general lower, approximately 8%, when platelets are isolated from the buffy coat without pelleting.[173] Interestingly, approximately 50% of all platelets are activated after 5 days of storage, whether prepared by the PRP or buffy coat methods. These observations suggest that while platelet pelleting used in the PRP method causes significant α-granule release, an obligatory degree of platelet activation occurs during storage regardless of the preparative technique. In another study, it was found that the higher the platelet count in the platelet concentrate, the greater the percentage of activated platelets at any given time.[174] After 5 days of storage, platelet activation averaged 15% in less concentrated, stored platelets (1×10^9/mL) and 30% in more concentrated units (1.4×10^9/mL); these percentages increased to 60% and 70%, respectively, by 10 days of storage.

P-Selectin and Platelet Recovery/ Survival Studies

It has been suggested that activated, P-selectin-positive platelets might be preferentially removed from the circulation after transfusion. Activated platelets first bind to leukocytes and are then eliminated, presumably through the mononuclear phagocyte (reticuloendothelial) system. This hypothesis was tested by isolating platelets from normal donors, storing them for 2 to 4 days under standard blood bank conditions, and then reinfusing the platelets. Pretransfusion platelet P-selectin expression was determined, and in vivo survival was estimated by ^{111}In labeling.[161] Platelet recoveries at 1 hour demonstrated a modest inverse correlation with the percentage of activated platelets expressing P-selectin ($r^2 = 0.30$; $P < 0.05$). As in other studies of platelet survival, other factors (pH, temperature, agitation) in addition to activation may have influenced platelet recovery. The recovery of activated platelets after transfusion was also studied in thrombocytopenic cancer patients. By quantifying the percentage of activated platelets in patients before and after transfusion and in the platelet concentrate, the observed recovery of activated platelets was compared with the predicted recovery, which was based on the increment in platelet count after transfusion. The observed recovery of activated platelets was always lower than predicted, averaging 38% of the predicted values and implying that activated platelets may be preferentially cleared after transfusion. These data suggest that increased platelet activation as measured by P-selectin expression may be related to poorer in vivo survival.

Proteolysis of Platelet Cytoskeletal Proteins during Storage

The platelet cytoskeleton plays a major role in maintaining platelet shape. It also assures the integrity of the external platelet membrane, which carries several important receptors.[175,176] Platelet cytoskeletal proteins undergo a degree of degradation during storage. However, the contribution of this "proteolysis" to the progression of the platelet storage defect is largely unknown. Certainly, deterioration of cytoskeletal proteins could negatively impact platelet structure and function. Moreover, protein degradation may play a role in platelet microvesicle formation during platelet storage.[172,177] There are a large number of platelet cytoskeleton proteins including actin, actin-binding protein (ABP), talin, vinculin, gelsolin, tubulin, and myosin heavy chain. Of these, actin is present in greatest abundance, constituting 15% to 20% of total platelet protein.

Actin Breakdown during Platelet Storage

When platelet products are stored under blood bank conditions, actin is cleaved into at least two fragments of approximately 28 kDa.[178] Amino acid sequencing has identified that these proteins are formed when actin is cleaved at the N terminus of residues Thr-106 and Ala-114. Actin fragments are generated when platelets are stimulated by the calcium ionophore A23187, in a reaction that can be inhibited by nonspecific protease inhibitors.[179–181] This finding suggests that actin is proteolyzed by the calcium-dependent neutral protease calpain. Degradation of other platelet cytoskeletal proteins during storage like ABP, talin, and vinculin may also be related to calpain activation. Specifically, ABP degradation products have been seen on immunoblots of 1-day-old platelets, providing further evidence that platelet activation begins during actual platelet preparation. After 6 days of platelet storage under blood bank conditions, ABP undergoes additional degradation as reflected by further generation of lower molecular weight breakdown products.

Calpain Activation and Platelet Microvesicle Formation

Platelets are exposed to shear stresses during their separation from blood as well as during agitated storage. These, and other physical stresses, appear capable of stimulating calpain generation. Calpain activation during storage may also promote platelet microvesicle (PMV) formation. Microvesicles are fragments of platelet membrane that are continuously formed during platelet concentrate storage.[177] Presumably, activated calpain promotes PMV formation by degrading actin and other cytoskeletal proteins, leading to a weakening of the actin-cytoplasmic membrane interface with resultant formation of microvesicles.[182] Despite these observations, the overall contribution of such proteases in the deterioration of platelets with storage remains unclear.

Non-Caspase-Dependent Platelet Apoptosis

Recent data suggest that apoptosis, possibly mediated through non-caspase-dependent mechanisms, may also play a role in platelet cytoskeletal changes during storage.[183–186] Apoptosis—programmed cell death—was first described by Kerr and associates in 1972[187] and was long held to be solely a property of nucleate cells. Only relatively recently was it appreciated that anucleate platelets likewise possessed extranuclear apoptotic machinery.[188] Many of the changes commonly found in apoptosis have been identified in platelets including apoptotic morphology, loss of mitochondrial function, activation of the effector caspase 3, microparticle formation, and elaboration of phosphatidylcholine (PC) on the platelet surface. Research findings on platelet apoptosis were recently summarized in a review by Leytin and Freedman.[186]

Modulation of Glycoprotein Ib and IIb/IIIa Expression during Storage

Changes in the expression of platelet-specific glycoproteins, such as GPIb and GPIIb/IIIa, occur during platelet storage. Over time the extracellular portion of GPIb can be cleaved by thrombin or plasmin, resulting in increased levels of the glycosylated portion of GPIb, glycocalicin, in the cell-free supernatant.[189] Despite an increase in plasma glycocalicin, however, platelet surface GPIb content remains relatively constant, although a distinct subpopulation of GPIb-negative platelets does appear over time.[189] Investigators have postulated that surface GPIb may be replenished through relocation of GPIb to the surface from an intracellular pool or a sequestered surface population.

Storage Conditions and Expression of Platelet Surface Receptors

Storage conditions may play a significant role in platelet surface receptor changes. Platelet products stored on an elliptical rotator will loose nearly 50% of their surface GPIb, whereas membrane GPIb on platelets stored on a circular tumbler rotator do not significantly decrease.[172] Therefore, comparisons made between studies of stored platelet concentrates must take into account storage and preparation protocols. Postprocessing manipulation of platelet concentrates may also decrease surface GPIb. For example, PCs exposed to high-dose (10,000 mJ/cm^3) ultraviolet B (UV-B) irradiation have significantly reduced surface GPIb expression as compared to untreated PCs.[190] By contrast, UV-B at these doses does not appear to affect GPIIb/IIIa surface density. Filtering platelets through various leukocyte removal filters also does not appear to appreciably alter the surface expression of GPIb or GPIIb/IIIa.[191]

Seven days of storage on elliptical and tumbler rotators causes platelet surface GPIIb/IIIa to increase slightly as measured by ^{125}I-labeled monoclonal antibodies.[172] Studies using flow cytometry and monoclonal antibodies directed against GPIIb/IIIa have similarly demonstrated increasing GPIIb/IIIa expression during platelet storage.[173] After 5 days of storage, mean surface expression of GPIIb/IIIa increased by 50% to 70% from baseline; expression increased by 300% or more when storage was extended to 10 days. A separate study found that preparation of platelets, especially the pelleting step, was largely responsible for the initial increase in surface GpIIb/IIIa.[174] Increased surface GPIIb/IIIa paralleled increases in β-TG release and surface expression of P-selectin, both of which reflect α-granule release. Because α-granules contain a pool of GPIIb/IIIa, it seems likely that the increase in platelet surface expression of GpIIb/IIIa is due to relocation of this protein from α-granule stores to the platelet membrane. Alternatively, loss of surface GPIIb/IIIa may occur during platelet storage as a result of protease degradation or formation of microparticles from the platelet membrane.[177]

Thus, potential losses of both GPIb and GPIIb/IIIa during platelet storage can be at least partially compensated for by release of intracellular pools or by sequestration from other sources. For example, fresh plasma can restore platelet GPIb surface expression and is a possible explanation for the preservation of platelet function after transfusion.[192] Alternatively, GPIb could be relocated from platelet storage pools or sequestered at vascular surfaces. Interestingly, the levels of GPIb after storage, although low, are not as low as those seen on platelets collected from individuals with Bernard-Soulier syndrome—a hereditary absence of GPIb receptors associated with a bleeding tendency. Thus, a critical level of these surface receptors may be required for platelet adhesion to the corresponding ligand.

POSTCOLLECTION PROCESSING

Leukoreduction

Platelets, like red blood cells (RBCs), should be transfused through standard blood administration filters—either a 170-μm "clot filter" or a 20-μm "microaggregate filter." Both filters trap larger debris such as clots, while the smaller pore microaggregate filter additionally traps finer particulate matter such as small aggregates of dead cells and fibrin strands. Neither removes white blood cells (WBCs). Filtration of platelets through microaggregate filters results in loss of less than 5% of the platelets, a loss attributed to the filter's void volume.[193]

Leukoreduction—the differential removal of WBCs from cellular blood components—is generally agreed to be beneficial because of the range of adverse patient effects that may arise from contaminating donor leukocytes in blood products. The most commonly accepted complications associated with high levels of contaminating WBCs include febrile nonhemolytic transfusion reactions (FNHTRs),[194] alloimmunization,[195,196] and CMV transmission.[197]

Development of Leukoreduction Filters

In the 1990s, highly efficient filters were developed that were capable of removing 3 to 4 $\log_{10}$ or more of all WBCs found in a unit of RBCs or platelets.[198,199] These filters are generally manufactured from a polyester fiber matrix to which various polymer chemicals are linked. The size of the polymer affects the degree to which WBCs are exposed to its surface and, thus, the efficiency of leukocyte removal. Filters that are designed to leukoreduce RBC units cannot be used to filter platelets because these filters nonspecifically adsorb both WBCs and platelets.[200] Therefore, filters have been specifically designed for leukodepleting platelet concentrates.[201]

Leukoreduction Strategies

Many countries have instituted, or plan to institute, universal leukoreduction of all cellular blood components, including platelets.[202–204] This strategy imposes an additional cost burden, and the added expense must be thoughtfully weighed against the additional benefits to patient care and outcomes.[205] Leukocyte reduction using filtration can be performed at the time of transfusion using a bedside leukoreduction filter (e.g., Baxter SEPACELL Platelet Leukoreduction Filter). It may also be performed as part of component manufacture—so-called prestorage leukoreduction—using inline filters contained in blood collection sets (e.g., Pall Leukotrap RC PL Whole Blood Collection, Filtration, and Storage Systems).

Leukoreduction and Prevention of Transfusion-Transmitted CMV Infection

The use of leukoreduced (LR) blood components, particularly prestorage LR products, as "CMV safe" versus serologically tested "CMV seronegative" products has drawn considerable attention in those communities that treat at-risk patient populations—particularly those with hematologic malignancies,[206]

solid organ[207] and stem cell[208] transplant recipients, AIDS patients,[209] and neonates.[210] CMV infection in these immunocompromised hosts has been associated with considerable morbidity and mortality. Studies conducted in the 1980s demonstrated that transfusion of blood products from CMV-seronegative donors significantly reduced the rate of transfusion-transmitted CMV (TT-CMV) infection.[211] For a period of time, many transfusion centers maintained dual inventories of CMV-seronegative and CMV-untested products. Later studies revealed that TT-CMV was mediated by passenger leukocytes harboring the virus.[212] With the advent of third-generation leukoreduction filters capable of removing 3-$\log_{10}$ WBCs, it was hypothesized that such reductions could lead to reduced rates of TT-CMV. This was confirmed by the landmark study by Bowden and colleagues[88] showing that the rates of CMV infection were nearly identical when seronegative stem cell transplant (SCT) patients were transfused with LR products versus seronegative products (2.4% vs 1.4%, $P = 0.50$). Much debate has ensued, and while data have demonstrated the effectiveness of leukoreduction in decreasing CMV antigenemia from donor blood and reducing TT-CMV rates,[213–215] some investigators continue to challenge the effectiveness of this strategy.[216,217]

Leukoreduction and Prevention of Febrile Nonhemolytic Transfusion Reactions

At the cellular level, lysosomal enzymes present in neutrophils are known to digest various platelet proteins. For example, elastase digests GPIb. During storage, the platelet NADPH oxidase system is activated, resulting in release of platelet-activating factor (PAF).[218] Cytokines released from lymphocytes are known to produce a variety of adverse effects in vivo. Platelet-poor supernatant plasma from stored platelet concentrates is more likely to produce febrile reactions than are platelets contained in the cellular fraction of the stored units of concentrates.[219] Other groups have shown that lymphocytes present in units of stored platelets produce cytokines such as interleukin-8 (IL-8), which may be partially responsible for febrile transfusion reactions.[220,221] Thus, removal of leukocytes before or early in storage (prestorage leukoreduction) may reduce this risk by removing the lymphocytes before they can synthesize or release various enzymes and cytokines.

Leukoreduction and Prevention of HLA Alloimmunization

Antigen-presenting cells (APCs) present in platelet concentrates appear to promote HLA alloimmunization that is responsible for one form of platelet refractoriness.[222] The adverse effects of neutrophilic enzyme discharge and lymphocyte cytokine release during platelet storage could be ameliorated by prestorage leukodepletion. Using a rabbit infusion model, it has been shown that supernatant plasma obtained from blood stored prior to filtration induces a significantly higher degree of alloimmunization than does plasma filtered before whole blood storage.[223] These results suggest that prefiltration may further decrease the incidence of HLA alloimmunization by preventing generation of soluble biological response modifiers, as well as by preventing the formation of platelet or RBC microparticles during storage. It is generally believed that viable donor APCs are needed to present donor HLA antigen to the recipient's T cells. Whether this mechanism would function with the infusion of plasma without donor APCs is not clear. In such cases, the recipient's APCs can also present transfused donor antigens. If so, removal of leukocytes before they shed HLA antigens into the stored plasma may be beneficial. Blood bags with RBC and platelet leukoreduction filters integrally attached so as to provide a closed system for prestorage leukocyte depletion at the time of collection are available and are being used more extensively.

Gamma Irradiation

Prevention of Transfusion-Associated Graft-versus-Host Disease

Cellular blood components are exposed to γ irradiation to prevent transfusion-associated graft-versus-host disease (TA-GVHD) in susceptible patients[224]—a nearly uniformly fatal complication of transfusion.[225] Until recently, the dose of irradiation used varied from 1500 to 5000 cGy (1 rad = 1 cGy), with most transfusion centers using doses between 1500 and 3500 cGy.[226] The FDA recommends that a dose of 2500 cGy be delivered to the mid-plane of a free-standing irradiation canister with a minimum dose of 1500 cGy delivered to any other point in the canister.[227] Platelets stored for 1 to 5 days and subsequently irradiated with 5000 cGy have been shown to maintain normal platelet function in vitro, morphology, platelet factor 3 activity, response to hypotonic stress and synergistic aggregation, β-thromboglobulin release, and thromboxane B_2 formation.[228] Irradiation with 5000 cGy causes a decrease in the initial recovery of fresh and stored platelets transfused into normal volunteers, although the platelets appear to survive normally.[229] In this study, the circulating platelets failed to neutralize the effects of aspirin on the recipient's bleeding time, however, the hemostatic effectiveness of these platelets in thrombocytopenic patients did not appear compromised. Subsequent studies have not confirmed any damaging effect of irradiation at these doses on platelets. Exposure of platelet concentrates to 3000 cGy followed by storage for 5 days has no significant effect on either in vivo platelet recovery or platelet survival.[230] Similarly, no detrimental effects on in vitro function were demonstrated in platelet units irradiated with 2000 cGy and stored for up to 5 days.[231] Evaluation of paired apheresis platelets stored for 5 days after receiving 2500 cGy on days 1 or 3 similarly showed no deleterious effects on in vivo recovery or survival or on in vitro properties of platelets.[232] In contrast to the negative effects of irradiating RBCs, which limits their shelf life, the 5-day storage period of irradiated platelets does not need to be shortened.[224] These observations are of practical importance because many transfusion services are not equipped to irradiate blood components just prior to transfusion. Therefore, they must maintain an inventory of irradiated platelets obtained from the collecting facility.

Ultraviolet Irradiation

Prevention of HLA Alloimmunization

Donor leukocytes contained in platelet products are considered to play a significant role in primary alloimmunization of recipients to class I major histocompatibility complex (MHC) antigens, which in turn may result in refractoriness-to-platelet transfusions.[233] It was originally shown over 30 years ago that lymphocytes exposed to sufficient doses of UV irradiation are unable to stimulate allogeneic cells in mixed lymphocyte culture (MLC) or to respond to mitogenic stimuli.[234] UV-C, which has the shortest wavelength (200 to 280 nm) and the greatest biological activity, has been found

to induce the formation of pseudopods at the platelet surface and to cause a degree of platelet aggregation.[235] Medium wavelength UV-B light (280 to 320 nm) has been shown to inactivate leukocytes in PCs. The UV-B doses needed to irreversibly damage WBCs depends on the UV source, the type of plastic container used, and the cross-sectional depth of the platelet concentrate volume.[236] PCs irradiated with 3000 J/m^2 UV-B and then stored for 5 days experienced no adverse effects on pH, hypotonic stress, or aggregation responses.[237] In addition, transfusing healthy volunteers with autologous platelets irradiated at this dose and stored for 5 days reveals equivalent platelet recovery, half-life, and survival as compared to control nonirradiated platelets.[238] However, irradiating pooled PCs with high-dose UV-B (100,000 J/m^2) results in a significant decrease in morphology score and osmotic recovery after 96 hours of storage. Expression of GPIb also declines by 60% at 96 hours after irradiation at the higher dose, with no alterations in surface GPIIb-IIIa expression.[190] Therefore, long-term storage of platelets after higher-dose UV-B irradiation is not recommended.

Results of one small study suggested that in vivo recovery and survival of autologous PCs irradiated with high-dose UV-B (15,000 J/m^2) are modestly reduced as compared to control platelets (7 vs 7.75 days, $n=4$).[239] Differences of this magnitude would not be clinically relevant. In the Trial to Prevent Alloimmunization to Platelets (TRAP), UV-B irradiation at 1480 mJ/cm^2 was shown to be equivalent to leukofiltration for decreasing the incidence of refractoriness to platelet transfusions in patients with acute myelogenous leukemia.[240] Long-wavelength UV-A (320 to 400 nm) light by itself is insufficient to inactivate leukocytes. However, UV-A at low doses activates 8-methoxypsoralen (8-MOP), transforming it into a potent DNA cross-linking agent capable of abolishing MLC activity.[241] Pretreating PCs with 8-MOP and UV-A irradiation can reduce the allogenicity of class I MHC antigen in mice without affecting platelet aggregation responses.[242]

Photochemical Treatment and Pathogen Reduction

The risk of viral TTD has steadily decreased with advances in donor screening and testing.[243] Despite these improvements, however, there remains a small residual risk of viral, bacterial, or protozoal transmission. Many potentially serious infectious agents are not directly screened for, and emerging pathogens such as West Nile virus demonstrate the ongoing potential for new risks to the blood supply.[244–246] Stringent donor screening and TTD testing offer significant, but incomplete, protection and are associated with both time and cost burdens that have prompted many experts in the field to champion for adoption of pathogen reduction (PR) strategies.[247] PR technology is already in active use in Europe,[248] although efficacy and patient safety concerns have slowed adoption in the United States.[249]

Spectrum of Pathogen Reduction Technologies

PR technologies encompass a heterogenous group of methods that differ with respect to their chemical and biological characteristics, the spectrum of pathogens against which they have activity, their efficacy of inactivation, and the blood components to which the method may be applied. The highly effective techniques developed to inactivate viruses in plasma, such as solvent and detergent treatment and heat sterilization,[250,251] are too harsh and cannot be applied to cellular blood components. Thus, alternative methods to inactivate infectious pathogens in cellular blood components such as platelets and RBCs are undergoing clinical development.[252]

Psoralen-Based Pathogen Reduction

Currently, one of the most actively investigated systems for PR of platelets utilizes the novel psoralen amotosalen HCl (previously known as S-59), which is photoactivated by long-wavelength (UV-A) ultraviolet light. Psoralens, a family of naturally occurring, small planar molecules, readily pass through cell membranes and viral capsids and reversibly intercalate into helical regions of DNA and RNA. On exposure to UV-A light, covalent crosslinks to the pyrimidines thymidine and cytosine form, resulting in blockage of DNA replication and RNA transcription of nucleic acids.[253] This results in the effective inactivation of viruses,[254,255] bacteria,[256] protozoa,[257] and leukocytes.[258] Photochemical treatment with amotosalen has been shown to be capable of inactivating high concentrations of cell-free HIV, proviral HIV, duck hepatitis B virus (a surrogate for HBV), bovine viral diarrhea virus (a surrogate for HCV), CMV, gram-positive bacteria, and gram-negative bacteria.[259,260] This technique can also inactivate *Trypanosoma cruzi*, *Plasmodium malariae*, *Borrelia burgdorferi*, and rickettsiae in PCs.[261]

Optimal PR using amotosalen requires resuspension of the platelets in a plasma-reduced medium, since plasma has been shown to interfere with the inactivation of viruses.[262] Additionally, after UV-A exposure, residual amotosalen remains in the product; although amotosalen is not mutagenic in the absence of UV-A,[263] the use of an S-59 reduction device or similar method is routinely practiced to remove unspent psoralen. Specific photochemical treatment (PCT) methods for platelets using amotosalen are well described.[256] The resulting products contain very low levels of residual amotosalen and free photoproducts. Following PR, the platelet products can be stored under routine conditions.

The safety profile of PR methods using amotosalen appears quite good. Extensive preclinical toxicologic studies have been performed using amotosalen-treated platelets and have shown no evidence of toxicologically significant CNS, renal, cardiac, or reproductive toxicity.[264,265] In addition, clinical trials of the INTERCEPT (S-59 psoralen system) system conducted in Europe[266] and the United States[267,268] have shown therapeutic equivalence between conventional and amotosalen-treated platelet products, as well as similar adverse reaction profiles. Data also suggest that amotosalen treatment may prevent transfusion-associated GVHD.[269–271]

Riboflavin-Based Pathogen Reduction

A second candidate PR system for use with platelets involves the use of riboflavin (vitamin B_2), an essential nutrient whose photoactivation properties have been extensively studied.[272] Riboflavin, like amotosalen, readily intercalates between DNA and RNA bases. On exposure to UV light in the 280- to 360-nm range, several photolytic processes occur including oxidation of guanosine through direct electron transfer, production of singlet oxygen, and generation of hydroxyl radicals. These collectively result in single-strand breaks and the formation of covalent adducts that inhibit replication.[273] Effective PR using riboflavin/UV-A methodologies have been reported against a broad spectrum of pathogens

including porcine parvovirus, cell-associated and cell-free HIV-1, intracellular HIV-1, gram-positive and -negative bacteria, and West Nile virus.[274,275] Preclinical toxicologic studies have shown no significant toxicity.[276]

Clinical studies with the Mirasol PRT (riboflavin/UV) system have shown some differences between PCT-treated platelet units and control units. In a study of leukoreduced apheresis platelets by Aubuchon and colleagues,[277] riboflavin/UV-treated platelet units demonstrated in vitro evidence of increased glycolysis and decreased pH during 5-day storage as compared to control platelet units, although glucose was not completely exhausted during this time and pH (7.02 ± 0.10, control 7.38 ± 0.07) was maintained at a level that did not interfere with platelet metabolism. Differences were likewise noted with in vivo parameters: treated platelets showed diminished recovery (50.0% ± 18.9, control 66.5% ± 13.4) and survival (104 ± 26 hours, control 142 ± 26 hours) compared with controls. These data were similar to those from previously published studies.[274,278]

Other Pathogen Reduction Agents

Other agents capable of photoinactivating viruses such as merocyanine 540 (MC 540), a heterocyclic polymethine dye, have adverse effects on platelet structure and function. In both the presence and absence of visible light, MC 540 has deleterious in vitro effects on platelets that include inhibition of platelet aggregation, a more precipitous decline in pH, and poorer morphology scores during platelet storage.[279,280] Thus, photoinactivation techniques must be rigorously evaluated to ensure that they do not harm platelet membranes or result in loss of normal platelet function.

BIOLOGICAL RESPONSE MODIFIERS

Febrile Reactions and Biological Response Modifiers

Pathogenesis of Febrile Nonhemolytic Transfusion Reactions

Many adverse effects of platelet transfusion therapy are related to the elaboration of various biologically active molecules by the constituents of platelet products or the blood recipient. These substances, often termed *biological response modifiers* (BRMs), are clearly involved in the pathophysiology of common nonhemolytic febrile transfusion reactions,[281,282] which occur in 4% to 30% of platelet transfusions. They also play a role in more severe immunohemolytic and septic transfusion reactions. The pathogenesis of febrile reactions was originally attributed to the presence of antibodies in the transfusion recipient that react with donor leukocytes.[283] Following binding of these antibodies to donor leukocytes, fever ensues through a cytokine-mediated inflammatory response that results in release of interleukin 1 (IL-1). Fever is then produced through IL-1 stimulated synthesis of prostaglandin E_2 (PGE_2) in the thermoregulatory center of the hypothalamus.[284]

Subsequent data, however, demonstrated that cytokines present in the plasma portion of PCs act as the primary agent for the development of febrile reactions.[285] Following platelet preparation, whether by the platelet-rich plasma, buffy coat, or apheresis methods, there is continued elaboration of cytokines by viable donor leukocytes.[286] PCs contain not only WBCs but a vast array of soluble proteins that have biological activity. It is not entirely understood what stimulates WBCs to produce cytokines during platelet storage. Platelets themselves could contribute to these reactions through the release of platelet-specific cytokines following activation or damage to platelets with component preparation and storage.[287] The major classes of BRMs include complement fragments, interleukins, chemokines, arachidonic acid metabolites, kininogens, and histamines (Table 23–3). There is also a wide array of other biologically active and inorganic compounds that are similarly capable of interacting with humoral and cellular receptors.

Biological Response Modifiers in Platelet Products

Direct and indirect evidence suggest a key role for BRMs in febrile, nonhemolytic transfusion reactions to platelet infusions. FNHTRs are seen in patients who are receiving their first blood transfusion and have not been pregnant.[288] Presumably, these patients would not have developed a secondary immune response from a prior exposure to foreign blood constituents. The incidence of platelet transfusion reactions may be related to the duration of platelet storage: reaction rates can be nearly double in 3- to 5-day-old platelets as compared to 1- to 2-day-old products.[219] These findings have been attributed to reactive substances contained in the plasma portion of stored platelet concentrates. Specifically, supernatant levels of IL-1β and IL-6 strongly correlate with the frequency of febrile reactions. Similar relationships between storage duration and febrile reaction rates have been found following transfusion of nonfiltered pooled platelet concentrates.[289] The incidence of allergic reactions does not appear related to storage time.

Specific chemical mediators thought to play a role in FNHTRs include cytokines, complement fragments, antibodies, and cell adhesion molecules.[290] Donor leukocytes can continue to produce cytokines after they are infused into a recipient, the so-called passenger leukocyte effect. Cytokines are synthesized and elaborated by donor leukocytes during storage, after which these preformed cytokines are infused during transfusion.[291] The latter mechanism, in vitro cytokine production during platelet storage, has received increasing support as the mechanism responsible for the majority of FNHTR.[292] Accordingly, many investigators have focused their research on modulating the effects of BRMs in platelet therapy. Most efforts are directed at limiting the formation of

Table 23–3 **Biological Response Modifiers (BRMs) Found in Platelet Concentrates**

Class	Examples
Complement fragments	C3a, C5a
Cytokines	
Interleukins	TNF-α, IL-6, IL-10, IFN-γ, IL-10, IL-4, TGF-β
Chemokines	IL-8, MCP-1, RANTES, β-TG, NAP-2, MIP-1β
Monokines	IL-1, IL-8, TNF-α, IL-6, IL-12
Anti-inflammatory cytokines	IL-1 receptor antagonist
Kininogens	Bradykinin
Histamine	
Other BRMs	Prostaglandins, nitric oxide, leukotrienes (LTB4), platelet activating factor

BRMs during platelet collection and processing, decreasing the formation of BRMs during platelet storage, and removing BRMs prior to or during platelet transfusion. Many of these techniques involve collecting platelets with little WBC contamination (process leukoreduction) or removing leukocytes from PCs shortly after their preparation (prestorage leukoreduction).

Leukoreduction and Biological Response Modifiers

Our understanding of the effects of BRMs in platelet therapy is largely derived from studies of leukoreduced blood components. Third-generation leukoreduction filters eliminate approximately 99.9% ($<5\times10^6$ leukocytes remaining per unit) of the WBCs found in a unit of whole blood. Generally recognized benefits of leukoreduction include reducing the incidence of febrile reactions, preventing transmission of cytomegalovirus, and decreasing alloimmunization to HLA antigens. Leukoreducing blood products, however, does not prevent allergic reactions.[293] Prestorage leukoreduction of RBCs has been shown to further reduce the likelihood of FNHTRs as compared to the use of bedside leukoreduction filters.[294] This study also suggested that FNHTRs are more common following infusions of single-donor apheresis platelets than of RBC transfusions—a finding that may be related to the storage of platelets at room temperature.

Several groups have shown that prestorage leukoreduction of blood components slows the accumulation of cytokines in platelet products and RBCs during storage. It is now clear that prestorage leukoreduction decreases the incidence and severity of FNHTRs by minimizing the production of cytokines by residual leukocytes. In particular, levels of IL-8 in PCs prepared by the platelet-rich plasma method and leukoreduced shortly after collection are much lower than in nonleukoreduced PCs after 5 days' storage.[220] Reductions of RANTES and C3a are also seen when PCs are filtered through third-generation filters that reliably reduce WBC numbers by 4 $\log_{10}$ per unit filtered.[295] The filter used in the latter study (PXL-8; Pall Corp.) did not remove the proinflammatory cytokines IL-1β and IL-6.

Direct Removal of Biological Response Modifiers by Leukoreduction Filters

The ability of certain platelet leukoreduction filters to remove the anaphylatoxins C3a and C5a, as well as the chemokines IL-8 and RANTES chemokines, has been studied. Levels of C3a, C5a, IL-8, and RANTES were reduced by filtration through the two bedside leukoreduction filters examined (PXL-8 and PXL-A; Pall Corp., East Hills, N.Y.), but not through a prestorage platelet filter (Sepacell PLS-5A; Asahi, Toyko, Japan).[296] IL-1β was not removed by any of these filters. These experiments, which used WBC-free plasma, demonstrate that binding of WBCs to filters is not necessary for the trapping or degradation of most BRMs. Earlier in vitro studies showed that C5a can be removed from plasma by peripheral blood leukocytes that contain high-affinity binding sites for C5a.[297] The binding of C5a to leukocyte receptors likely represents a physiologic mechanism that protects cells from this potent anaphylatoxin. Similarly performed studies have shown little accumulation of IL-1β, IL-6, IL-8, or TNF-α in leukoreduced platelet concentrates.[221] Data from additional studies have shown that the frequency of reactions is significantly higher in patients receiving poststorage WBC-reduced platelets (25.8%) than plasma-depleted platelets (17.0%).[298] In this study, IL-6 levels of platelet products appeared to be associated with the risk of reaction; however, IL-6 levels were not measured in patients during or after transfusion, and other cytokines that have been implicated in febrile reactions were not examined.

Hypotensive Reactions to Platelet Transfusions: Role of Bradykinin

Severe hypotensive reactions have been reported following platelet transfusion therapy.[299] The most serious reactions appear to occur in patients receiving angiotensin-converting enzyme (ACE) inhibitors who are transfused with platelets through a bedside leukoreduction filter.[300] The reactions were more common when filters bearing a net negative surface charge were used. While the pathogenesis of this syndrome remains unclear, it appears in some cases to be due to activation of factor XII and the prekallikrein-kinin cascade by negatively charged surfaces, resulting in bradykinin production.[301] Bradykinin (BK) produces adverse in vivo effects such as hypotension, abdominal pain, and facial flushing, without fever or chills. In most cases, it is possible to distinguish these reactions from febrile reactions and transfusion-related acute lung injury. However, these reactions must be promptly recognized.

ACE is identical to kininase II, an enzyme that degrades bradykinin. Accordingly, blocking kininase II prolongs the half-life of bradykinin such that clinical symptoms can develop in susceptible patients.[302] BK levels have been directly measured in donors undergoing plasmapheresis procedures[301] and in patients transfused with platelets through leukoreduction filters.[303] In the latter study, platelet-recipient BK levels transiently increased during the first 5 minutes when platelets were administered through a negatively charged filter (PL-50H; Pall Corp., Glen Cove, N.Y.). BK levels were particularly high in two patients with diminished ACE-inhibitor activity. Since bradykinin has a half-life of 15 to 30 seconds, prestorage leukoreduction, as opposed to bedside leukoreduction, should eliminate reactions due to BK generation from contact with the filter biomaterials. Such patients could benefit from receiving blood that has been either prestorage or in-laboratory leukoreduced, as opposed to being infused through a bedside leukoreduction filter.

In addition, a metabolic abnormality that affects des-Arg^9-BK degradation has been identified in several patients with severe hypotensive transfusion reactions.[304,305] Des-Arg^9-BK is an active metabolite of BK that is primarily inactivated by ACE and aminopeptidase P. With ACE inhibition, the half-life of des-Arg^9-BK, not BK, has been shown to be significantly higher in patients with pronounced hypotensive transfusion reactions when compared to control transfusion recipients. These findings suggest that failure to metabolize active vasodilatory peptides could contribute to transfusion reactions. However, they do not imply that bedside leukoreduction of blood components is absolutely contraindicated in patients on ACE inhibitors.

PLATELET TRANSFUSION THERAPY

Early in the 20th century, freshly drawn whole blood was the only source of viable platelets.[306] Although whole blood was neither a convenient nor an optimal source of platelets, such

transfusions reportedly reduced bleeding times and halted hemorrhage in thrombocytopenic patients. Platelet products became widely available only after the development of plastic collection and storage containers in the late 1960s and early 1970s, which allowed the separation of platelets from whole blood.[307] These products contained large numbers of viable platelets in a relatively small volume. Oncology patients utilize the majority of platelet products produced, and the increasing number of platelets used over the past two decades was in patients being supported during chemotherapy. Significant numbers of platelet products are also provided to trauma, surgical, and solid-organ transplant patients.

Indications for Platelet Transfusion

Platelet transfusion therapy is indicated for the prophylaxis or treatment of bleeding in patients with rapidly decreasing or critically decreased circulating platelet counts or in patients with functionally abnormal platelets.[1] In practice, most platelets are transfused to nonbleeding thrombocytopenic patients as a prophylactic measure.[308] Thrombocytopenia can result from myriad causes including marrow suppression (e.g., due to drugs, irradiation, infiltration, intrinsic marrow disease such as myelofibrosis), massive transfusion (dilutional thrombocytopenia), or immune destruction (e.g., immune thrombocytopenic purpura, thrombotic thrombocytopenic purpura, neonatal alloimmune thrombocytopenia). Patients with congenital or acquired platelet disorders, such as Bernard-Soulier syndrome or platelet storage pool deficiency, may also benefit from platelet transfusion. These individuals will frequently have normal platelet counts but diminished platelet function that is inadequate for normal hemostasis. Platelet transfusions are also considered in disseminated intravascular coagulation (DIC), during or following cardiopulmonary bypass, and to support patients undergoing extracorporeal membrane oxygenation (ECMO).

Despite vast clinical experience, few trials have been conducted to investigate the effectiveness of platelet transfusion therapy in controlling and preventing thrombocytopenic bleeding.[309,310] Thus, practices followed for platelet therapy often vary between and within medical facilities. This has resulted in a number of clinical controversies that have not been entirely resolved (Table 23–4). For example, it is unclear at what platelet count a nonbleeding patient should receive prophylactic platelet transfusions. Additionally, the optimal dose of platelets for an individual patient has not been clearly defined. Some practitioners advocate larger doses of platelets than those routinely provided (e.g., 10 WB-Plts instead of 4 to 6 WB-Plts). A variety of separation techniques have been developed to prepare platelets, each of which has certain advantages and disadvantages. Platelets isolated by each of the commonly used methods, however, have been successfully used in the clinical arena. Finally, a number of strategies have been employed to manage platelet refractory patients. These patients are often difficult to manage, and they can consume large quantities of platelets.

Table 23–4 **Clinical Controversies in Platelet Transfusion Therapy**

Topic	Controversy
Prophylactic platelet transfusions	Higher versus lower platelet transfusion triggers
Platelet dosing	Larger versus smaller platelet doses
Platelet preparation and product selection	ABO-matched versus unmatched platelet concentrates
	Fresh versus stored platelet concentrates
	Single donor platelets by apheresis versus pooled donor platelet concentrates
	Decreased exposure to infectious agents in single donor units
Platelet refractory patients	Crossmatched versus HLA-selected platelets

Prophylactic Platelet Transfusion

It is now generally accepted that the decision to transfuse platelets, or any blood product, should almost never be based solely on transfusion thresholds (or "transfusion triggers"). Patient factors should always be considered when deciding when an individual patient should be transfused. These factors may include the patient's primary disease, the presence of fever or sepsis, concurrent medications, and overall coagulation status.[311] Until recently, physicians typically transfused platelets to maintain a patient's platelet count above 20,000/μL. This level was believed necessary to prevent spontaneous bleeding.[312] However, serious spontaneous bleeding is unusual unless platelet counts fall below 5000/μL in the absence of other irregularities (e.g., aspirin use, decreased clotting factors) of the hemostatic system.[313] In fact, the earliest studies of the effectiveness of prophylactic platelet transfusions were limited by the widespread use of aspirin as an antipyretic agent, before the antiplatelet effects of this drug were recognized.

Determination of Optimal Platelet Transfusion "Trigger"

Other difficulties have hindered efforts to determine an optimal prophylactic platelet transfusion "trigger." First, serious thrombocytopenic hemorrhage is unusual, even at extremely low platelet counts. This fact was recognized early in the history of platelet transfusion therapy. Results of an early small clinical trial suggested that RBC usage and major bleeding were no different in patients who received prophylactic platelet transfusions at the 20,000/μL threshold as compared to those transfused only when bleeding from sites other than the skin or mucous membranes occurred.[314] Second, it is difficult to quantify minor clinical bleeding. Investigators have estimated stool RBC loss by ^{51}Cr RBC labeling as an indicator of spontaneous bleeding. One study using such a technique found that patients with aplastic anemia did not have significantly elevated stool blood loss until platelet levels dropped below 5000/μL.[315] Finally, platelet counts, as determined by automated counters or manual methods, are less reliable in severely thrombocytopenic patients.

During the past decade, a number of studies have been performed that were designed to more clearly define platelet transfusion thresholds. In one of the earlier studies, Gmur and colleagues prospectively followed 102 consecutive patients with acute leukemia.[316] Patients with platelet levels <6000/μL received prophylactic platelet transfusions, whereas those with levels >20,000/μL were transfused only when major bleeding developed or before invasive procedures. Intermediate thresholds included 6000 to 11,000/μL for patients with minor bleeding or fever and 11,000

to 20,000/μL for those with coagulation disorders and prior to minor procedures. Overall, 31 episodes of major bleeding occurred on 1.9% of total study days when platelet counts were <10,000/μL and on 0.07% of study days when counts were 10,000 to 20,000/μL. The investigators suggested that prophylactic levels of 5000/μL were safe in the absence of fever or bleeding. However, it was noted that several serious bleeds occurred in patients in the 6000 to 10,000/μL groups who did not receive prophylactic transfusions.

Bleeding Risk and Platelet Transfusion Needs in Thrombocytopenic Patients

Numerous prospective trials have compared the bleeding risks and platelet transfusion needs of thrombocytopenic patients. Most of these have grouped patients using 10,000/μL and 20,000/μL thresholds. In a nonrandomized trial, Gil-Fernandez and coworkers found no difference in bleeding using the 10,000/μL or 20,000/μL threshold in 190 bone marrow transplant recipients.[317] Heckman and associates randomized 78 patients with acute leukemia to the 10,000/μL or 20,000/μL threshold and could demonstrate no difference in bleeding between these two levels.[318] Similarly, Wandt and associates were unable to demonstrate a difference in bleeding risk when they prospectively compared transfusion thresholds in 105 patients with acute myeloid leukemia (AML).[319] Finally, in a large, randomized, multi-institution study of 255 patients with newly diagnosed AML, Rebulla and colleagues found no difference in major bleeding or in RBC transfusions when patients were transfused at the 10,000/μL or 20,000/μL threshold.[320] Although most of these studies were limited to patients with acute leukemia, similar studies performed in other patient groups, such as those with severe aplastic anemia[321] or following allogeneic marrow transplantation,[322] have shown that platelet thresholds can be safely lowered.

These studies suggest that there are no clear differences in serious hemorrhage or hemorrhagic death when the platelet transfusion trigger is set below 20,000/μL. When lower prophylactic platelet transfusion thresholds are used, recipients are exposed to less donor blood and the potential complications of such a transfusion. Despite the results of these studies, there remains no clear consensus on the clinical indications for prophylactic platelet transfusion. Accordingly, there is wide variation in the thresholds selected for prophylactic platelet transfusions.[323] For most patients, the lower 10,000/μL threshold is likely as safe as higher levels. Patients with other risk factors for bleeding such as fever and sepsis are probably best transfused at higher thresholds, although specific triggers for these groups of patients have not been defined. In addition, profound anemia can alter hemostatic capabilities and, accordingly, should be avoided in severely thrombocytopenic patients.[324] Platelet counts above 20,000/μL are indicated prior to invasive procedures. Typically, platelet counts are increased to >50,000/μL before lumbar puncture, indwelling catheter insertion, thoracentesis, liver biopsy, or transbronchial biopsy.[325] However, some data suggest that adults with acute leukemia may tolerate lumbar puncture (LP) without serious complication when platelet counts are ≥20,000/μL,[326] and children with acute lymphoblastic leukemia may tolerate LP without serious complication with platelet counts <10,000/μL.[327] Platelet transfusions are usually not necessary before bone marrow aspiration/biopsy if adequate surface pressure can be applied to the site after the procedure.

Platelet Dosing

Doses of platelets, as determined by the number of platelets in single or pooled PCs, have not been standardized. In practice, a single dose of transfused platelets generally contains approximately 3×10^{11} platelets, corresponding to 1 AD-Plt product or 5 to 6 pooled WB-Plt units. The optimal adult dose of platelets has not been clearly established, and doses are often determined based on factors unrelated to efficacy, such as cost and availability.[328–330] For example, an adult's body weight is not usually considered when determining the number of platelets to administer. In general, the higher a patient's post-transfusion platelet increment, the longer the interval will be before the next platelet transfusion is required. Endogenously produced platelets normally survive approximately 9 to 10 days in the absence of diseases that decrease platelet survival. Transfused platelets do not circulate this long in thrombocytopenic patients, as they are more rapidly consumed, for instance, to maintain vascular integrity. At platelet counts below 100,000/μL, a direct relationship exists between lower platelet counts and shorter platelet life span in the circulation.[331] For this reason, patients undergoing chemotherapy for various malignancies often require platelet transfusions at least every 3 days.[331] During periods of severe bone marrow hypoplasia, daily platelet transfusions are often required.

Large/Infrequent versus Small/Frequent Platelet Dosing Strategies

Several transfusion specialists advocate transfusing doses of platelets larger than the standard 6 WB-Plt pool, albeit at longer intervals between transfusions (e.g., 10–12 WB-Plt units every 2–3 days). The rationale for this practice is largely based on decreasing the number of individual transfusion episodes. This is more convenient in outpatient settings. As expected, it is possible to obtain higher post-transfusion platelet increments by transfusing higher platelet numbers.[332,333] However, it is unclear whether this practice is more effective than standard platelet doses in reducing the risk of spontaneous bleeding. Alternatively, smaller doses of platelets transfused at shorter intervals (e.g., 3–4 WB-Plt per transfusion) may reduce the total number of platelets required during a patient's thrombocytopenic period.[334] This strategy could decrease the overall number of platelets needed for a large patient population and decrease the number of exposures for an individual patient. Thus, smaller platelet doses may be more economical, but this practice has been criticized for possibly increasing the number of individual transfusions, which increases overall costs.[335] Therefore, an "optimal" dose of platelets has not been clearly defined, and transfusion practices will likely remain largely based on local preferences, which will often be heavily influenced by costs and supply.

Platelet Preparation and Product Selection

Platelet Surface Antigens and Immune Considerations

Platelets express a wide variety of surface antigens including the ABH, Lewis, P, and Ii blood group antigens; MHC class I HLA-A, -B, and -C antigens; and platelet-specific, human platelet antigens (HPAs).[336,337] Those that are most relevant to allogeneic platelet survival are the ABH, class I HLA, and HPA antigens. Interestingly, the presence of recipient antibodies directed against these antigens does not imply that all platelets

carrying these antigens will be rapidly destroyed. Platelet survival is clearly decreased when recipients with higher-titer anti-A or anti-B IgG antibodies in their plasma are transfused with platelets carrying one of these antigens. This incompatibility can be avoided by using ABO-identical platelets and should be considered as a first step in patients who are not responding appropriately to platelet transfusions.[338] Unfortunately, ABO-identical platelets are often not available during blood shortages. Transfusing ABO-incompatible, apheresis-derived platelets does not usually produce measurable hemolysis in adults, although significant hemolysis has been reported, especially in patients with small plasma volumes.[339,340]

Efficacy and Availability of Platelet Preparations

There appears to be little difference in the efficacy of platelet transfusions whether the concentrates are prepared from platelet-rich plasma or from buffy coats or are collected by apheresis.[341] The decision to use any of these products—or a mixture of such products—is often based largely on cost and availability. Advocates of BC WB-Plts, the technique widely practiced in Europe, note that cytokine production is lower in such concentrates.[342] BC WB-Plts have also been reported as less activated immediately after preparation. However, this difference is not appreciable after storage for 48 hours, and transfusing such products does not imply improved 5-day post-transfusion platelet recovery.[40,174] Thus, although various in vitro measurements of platelet concentrates compared by any technique may differ, these differences are not usually associated with decreased platelet survival in vivo. Human transfusion studies are difficult to perform and compare for several reasons, one being that thrombocytopenic patients often have extremely variable responses to platelet transfusion.[343]

Use of Apheresis Platelet Products

Many blood centers provide only platelets collected from apheresis donors on the basis of several theoretical benefits. AD-Plt transfusions decrease donor exposure, which theoretically could reduce the risk of transfusion-associated infection. Donor testing, however, has improved to the point that the most important human viruses are reliably detected in potentially infectious blood donors. NAT for viruses has dramatically reduced the risk of viral transmission, primarily by shortening the "window period" from the time of initial infection to the earliest point of detection.[243] This fact makes "limiting donor exposure" more difficult to justify. Use of AD-Plt products has also not been shown to reduce rates of alloimmunization,[89] although the benefits of leukoreduction have clearly been established.[344] Platelets prepared by apheresis are usually more expensive than those prepared from single whole-blood donations because of equipment and personnel costs for such a collection. Finally, there are risks to the apheresis platelet donors themselves inherent to this collection technique.[345]

Management of Platelet-Refractory Patients

It has long been recognized that a subset of patients who receive long-term platelet therapy develop progressively poorer responses to transfusion, marked by the rapid destruction of transfused platelets.[346] Platelet refractoriness arises from any condition that results in premature removal of platelets from the circulation. These conditions are often classified as immune-mediated and nonimmune-mediated based on the presumed mechanism of platelet destruction (Table 23–5).[343,347] Overall, nonimmune platelet destruction caused by splenomegaly (platelet sequestration), antibiotic treatment (e.g., amphotericin B), and infection are more common than immune-mediated causes.[348,349] From a practical standpoint, the effects of amphotericin B on platelet survival can be mitigated by transfusing platelets at least 2 hours after completing amphotericin infusion.[350] Antibody-related platelet destruction is most often related to the development of HLA-specific antibodies in response to foreign donor HLA antigens.[81,351] Presumably, these antibodies coat donor platelets that carry antigens these immunoglobulins are capable of recognizing.[352] The antibody-coated platelets are then removed by the reticuloendothelial system or through mechanisms involving platelet activation and deposition on endothelial surfaces.[353] Less commonly, patients develop platelet-specific antibodies.[354,355]

Table 23–5 Conditions Associated with Rapid Destruction of Transfused Platelets

Immune-Mediated	Non-Immune-Mediated
HLA class I alloantibodies	Splenomegaly
Platelet-specific alloantibody formation	Drugs (amphotericin B, other antibiotics)
Platelet-specific autoantibodies	Sepsis and fever
Circulating immunocomplexes	Disseminated intravascular coagulation
	Graft-versus-host disease

Strategies used to manage platelet refractory patients vary across institutions and are often based on the availability of specialized testing and platelet products.[356] Initial evaluation should include determination of several recent 1-hour, post-transfusion corrected count increments (CCIs)[357] to assess response to transfusion and review of the patient's chart to rule out nonimmune etiologies of refractoriness. In confirmed refractory but uncomplicated nonbleeding patients, it may be possible to simply withhold platelet transfusion and defer unnecessary invasive procedures. In patients in whom platelet transfusion is unavoidable—such as those with active bleeding or prior to an invasive procedure—several strategies have been advocated.

Large-Volume, ABO-Compatible, and Fresh Platelet Transfusion

A first maneuver can simply be to increase the number of platelets transfused (e.g., 6–12 random donor platelets per pool or 2 single-donor platelets by apheresis). Additionally, ABO-compatible platelets can be used, particularly in group O patients with known high titers of anti-ABO antibodies.[358] In practice, ABO-compatible platelets may not be readily available, although their potential benefit has long been established.[359] Likewise, "fresh platelets" less than 48 hours postcollection have been advocated based on storage time versus post-transfusion recovery studies.[360] Data supporting this strategy are less well established, and the requirement for mandatory TTD and bacterial testing has all but staunched the availability of fresh platelet products. If these relatively simple methods have been exhausted without benefit, more specialized platelet products may be required, including HLA-selected, HLA antigen-negative, and crossmatch-compatible platelet products.

HLA-Selected ("HLA-Matched") Platelets

In patients for whom HLA-selected platelets are being considered, identification of anti-HLA antibodies in the

patient should, ideally, be documented owing to the difficulties frequently encountered in obtaining such products. Provision of HLA-selected platelets requires that the patient be HLA typed; it also necessitates communication with the blood supplier to identify potential donors. The HLA system is extremely polymorphic and thus, a pool of 1000 to 3000 or more HLA-typed donors is needed to maximize the likelihood of an ideal platelet "match."[361] Platelet products are usually collected by apheresis and selected on the basis of degree of match for HLA-A and HLA-B types of donor and recipient, which is expressed as a match grade of A–D and R (random).[362] The best CCIs occur with grade A (4-antigen match), B1U (3-antigen match, 1 antigen unknown), and B2U (2-antigen match, 2 antigens unknown), although mismatches for some antigens that are poorly expressed on platelets, such as B44 or B45, have not been associated with poor response. HLA-C antigens are only weakly expressed by platelets, and mismatch of this antigen does not appear to significantly influence platelet survival.[363] The use of HLA-selected platelets in patients who are not alloimmunized for the purpose of preventing HLA alloimmunization does not appear warranted.[364,365]

HLA Antigen-Negative Platelets

Alternatively, if anti-HLA antibodies are present, their specificities can be determined and matched donors selected whose platelets lack the corresponding antigen. This method has been termed the *antibody specificity prediction* (ASP) method.[366] Comparison of platelets selected by the ASP method versus HLA-selected, crossmatched, and random (control) platelets demonstrated therapeutic equivalence for the ASP-matched, HLA-selected, and crossmatched products and superiority to randomly selected platelets. An additional benefit of the ASP method is the relative greater ease with which donors can be identified from a pool of potential donors.

Crossmatched Platelets

An alternative to HLA-selected or HLA antigen-negative platelets is crossmatch-compatible platelets. Platelet crossmatching may be performed using a solid phase system that involves incubating a sample of patient serum or plasma with donor platelets that have been anchored to the solid medium; reactivity is determined using indicator RBCs.[367] Flow cytometric methods have also been described.[368,369] Similarly to traditional RBC crossmatching, compatibility is based on the presence or absence of reactivity. In theory, crossmatching is more "sensitive" than HLA matching owing to the detection of *any* reactive antiplatelet antibodies, including anti-HLA, anti-HPA, antiplatelet glycoprotein (e.g., GPIIb), and anti-ABO. An incompatible platelet crossmatch predicts a poor response (platelet increment) in over 90% of transfusions. Conversely, a compatible crossmatch does not guarantee good survival—a compatible crossmatch is predictive of a successful transfusion only 50% to 60% of the time.[370,371] For this reason, large collection facilities may combine multiple approaches: platelet units are selected for crossmatch based on the class I HLA types of the recipient and potential donor. This approach is also of potential use in the unusual patient who has developed both HLA and platelet-specific antibodies. Other approaches that have been proposed to transfuse heavily alloimmunized patients include techniques to reduce class I HLA antigen expression on platelets.[372,373] These methods, which are largely based on eluting HLA antigens, are not available for routine clinical practice.

PLATELET SUBSTITUTES

Several products have been explored as alternatives to liquid platelet concentrates stored at 22° C. These "platelet substitutes" are, in general, either derived from platelets themselves or synthetic in nature. Platelet substitutes are designed to mimic the normal hemostatic properties of intact human platelets. Other advantageous properties of platelet substitutes include (1) an ability to retain efficacy when sterilized to prevent bacterial or viral infection; (2) a long, biologically active shelf life; (3) few specialized storage requirements; and (4) ease of preparation and administration. Substitutes should be hemostatically effective in vivo without causing dangerous thromboses and, in addition, be nonimmunogenic. Novel products derived from human platelets include platelet-derived microparticles, lyophilized platelets, and cryopreserved (frozen) platelets. Synthetic platelet substitutes include RBCs carrying surface-bound fibrinogen or surface-bound arginine-glycine-aspartic acid (RGD) peptides, fibrinogen-coated microspheres, and liposome-based agents.[65,374]

Platelet-Derived Microparticles

Platelet microparticles (PMPs) are platelet membrane microvesicles that form spontaneously during platelet storage. They have also been identified in fresh frozen plasma and cryoprecipitate. PMPs are strongly procoagulant and retain many of the biological properties of intact platelets. Specifically, they can both adhere to vascular endothelium and enhance platelet adhesion.[375] PMPs range in size from 0.1 to 1.0 μm in diameter and are identified based on their expression of surface receptors for platelet/endothelial interactions including glycoprotein IIb/IIIa, Ib/IX, and P-selectin.[170] Early studies in the late 1950s using infusions of platelets disrupted by sonication were discouraging.[376] This product had no apparent hemostatic effect in thrombocytopenic dogs and produced significant tachycardia and hypotension in recipients. More recently, human "infusible platelet membranes" (Cyplex; Cypress Bioscience, San Diego, Calif.) have been developed and tested in animal models.[377] This material is prepared from outdated platelets which are lysed by freeze-thawing, virally heat inactivated for 20 hours at 60° C, and finally sonicated. The fragments are then formulated with a preservative solution, lyophilized, and stored at 4° C; the product is reported stable for 3 years. The resulting spherical vesicles measure <1 μm in diameter and express detectable GPIb but not GPIIb/IIIa. This preparation has a phospholipid content similar to that of natural platelets, retains so-called platelet factor 3 (PF3) activity, and may have reduced class I HLA expression.[378] Studies have demonstrated shortening of the bleeding time in thrombocytopenic rabbits.[377] There is preliminary evidence that platelet membrane fragments prepared in this fashion are tolerated by human recipients and possess hemostatic effectiveness.[379] Human phase I and II clinical trials have shown no appreciable toxicity. This product, however, has not been licensed by the FDA because of the difficulties in demonstrating efficacy. Measurement of postinfusion platelet count increments is not possible because they consist of platelet fragments that are not routinely measured. In addition, it is difficult to quantify the effects of any platelet substitute in thrombocytopenic patients who typically have other conditions associated with a bleeding tendency.

Lyophilized Platelets

The process of lyophilization—rapidly freezing a substance at an extremely low temperature and then dehydrating in a high vacuum—has been investigated as a means of long-term platelet storage. In fact, studies of rehydrated lyophilized platelets were originally performed in the 1950s. Unfortunately, these studies failed to demonstrate hemostatic efficacy in animal models of thrombocytopenia.[380] A more recently developed lyophilization procedure appears to allow better preservation of platelet structure.[381] This technique involves fixing washed platelets in 1.8% paraformaldehyde, followed by freezing in 5% albumin, and lyophilization at −20°C to −40°C. The resulting "fixed and lyophilized" platelets retain important hemostatic properties after rehydration in studies of thrombocytopenic rats and canine models of von Willebrand disease. Their ultrastructure by electron microscopy is similar to that of fresh platelets, and they also express the glycoprotein surface receptors GPIb and GPIIb-IIIa, albeit at decreased concentration. Reconstituted, lyophilized platelets appear capable of supporting thrombin generation and facilitating fibrin deposition of exposed vascular endothelium in a vascular perfusion model.[382]

More recent data from human and baboon subjects suggests possible poorer in vivo and in vitro performance characteristics. In a study by Valeri and colleagues using paraformaldehyde-treated lyophilized reconstituted platelets,[383] human lyophilized platelets failed to aggregate to the dual agonists arachidonic acid and adenosine diphosphate (4% aggregation vs 84% fresh control); weakly aggregated with ristocetin (27% aggregation vs 93% fresh control); and failed to produced thromboxane A_2, increase surface expression of P-selectin, increase surface expression of GP IIb/IIIa, or decrease expression of GP Ib with agonist stimulation. However, the lyophilized platelets did demonstrate greater accumulation of factor V (FV) on their surface after recalcification as compared with fresh controls. Thus, modifications to the platelet membrane during processing appeared to interfere with both platelet aggregation and thromboxane production.

Additional data from this group looking at in vivo characteristics show similar differences between fresh control platelets and reconstituted lyophilized platelets.[384] Survival studies in a baboon model using either biotin-X-N-hydroxysuccinimide or ^{111} In oxine–labeled platelets showed marked differences in in vivo survival; whereas fresh platelets showed greater than 50% survival at 48 hours postinfusion and remained detectable at 6 days, reconstituted lyophilized platelets were rapidly cleared from the circulation and undetectable beyond 15 minutes. Similarly to the prior study, the lyophilized platelets demonstrated greater procoagulant activity immediately following infusion than fresh controls. Levels of surface-bound FV were five times greater at 1 minute postinfusion in lyophilized platelets than in fresh controls.

At present, the clinical use of lyophilized platelets remains unclear owing to concerns regarding the toxicity, in vivo survival (short in vivo life span), thrombogenicity, and reticuloendothelial blockade of such preparations. Clinical trials utilizing reconstituted lyophilized platelets have not, as yet, been performed.

Cryopreserved Platelets

Cryopreservation has been used to store RBCs units since the 1960s. However, similar techniques evaluated for preserving platelets at low temperatures have been less successful. Platelets that are frozen or stored for prolonged periods at 4°C demonstrate abnormalities in aggregation, hypotonic stress response, clot retraction, and most importantly in vivo survival. These changes are related to irreversible cytoskeletal and membrane alterations.[385] Adverse effects of freezing platelets could be minimized by using high concentrations of a cryoprotectant; however, cryoprotectants themselves can harm platelets. These effects can result from direct chemical damage and osmotic changes that develop as the cryoprotectant crosses the cell membrane.

Cryopreservative Agents

A number of compounds have been evaluated as potential platelet cryoprotective agents including glucose, dimethyl sulfoxide (DMSO, Me_2SO), propylene glycol, polyvinylpyrrolidone, hydroxyethyl starch, polyethylene glycol, ethylene glycol, and others.[386] Propane-1,2-diol (propylene glycol), which is an effective agent for other hematopoietic elements, has a higher permeability rate than glycerol and is an ineffective platelet cryoprotectant.[387] Glycerol, used extensively for RBC cryopreservation, has little direct toxic chemical effects on platelets at the concentrations needed for effective protection. However, this compound enters the cell relatively slowly, resulting in severe osmotic damage. Use of a 5% glycerol–4% glucose solution may minimize freeze-thaw platelet loss and in initial studies, preserved platelet function.[388] Despite these precautions, adverse effects of freezing on in vitro platelet function have been demonstrated. This damage consists of platelet morphologic and ultrastructural changes, decreased ATP levels, an inability to undergo the release reaction or aggregation, decreased recovery from hypotonic stress, and decreased in vivo recovery.[389,390] Modifications of the original procedure, including optimization of the platelet count prior to freezing and use of a nonplasma diluent, did improve in vitro function.[391] Attempts to adapt platelet cryopreservation using glucose-glycerol solutions for clinical use have, as yet, been unsuccessful.[392]

DMSO-Based Cryopreservation

DMSO, used widely as a cryopreservative for human progenitor (stem) cells, rapidly penetrates the platelet membrane and has less of an osmotic effect than glucose-glycerol. In addition, both in vitro and in vivo studies suggest that DMSO is a more effective cryoprotective agent than glycerol.[393] Long-term studies have shown that DMSO-preserved platelets remain functional when stored for 3 years at −80°C.[394] However, cryopreservation with 5% to 6% DMSO does result in a clear loss of platelet structure and function in terms of platelet morphology, aggregation responses, and platelet recovery following transfusion.[395] The average posttransfusion recovery of cryopreserved platelets is approximately 50% to 70% that of fresh platelets; those platelets that do survive the freeze-thaw cycle appear to circulate normally.[379] The nearly 50% of platelets that are damaged during cryopreservation become unresponsive to various platelet agonists. In addition, there is a decrease in the content of secretory granules and an almost complete absence of the metabolic activity typically seen after platelet activation. It has been postulated that these findings reflect a defect in the stimulus-response coupling mechanisms that follow plasma membrane damage. Although these effects generally appear equally distributed among subpopulations of platelets, larger platelets may be most capable of retaining normal

aggregatory responses.[396] Platelets stored frozen in liquid nitrogen with DMSO as a cryoprotectant have lower adhesive capacity in vitro as compared with fresh platelets from the same platelet unit.[397]
